Virtually all gulls nest in colonies, which may contain anything from a few pairs to tens of thousands or even occasionally over 100,000 pairs, sometimes densely packed together, though usually more open in the case of larger gulls. Nest density is usually highest in the centre, and the largest colonies tend to be divided into smaller subgroups. Colonial nesting is a useful anti-predator strategy: so many eyes and ears mean that a predator is spotted early, alarm calls are given, and the colony can be actively defended by communal mobbing and attacks. Gull colonies often attract other, unrelated species, including, for example, grebes, herons, cormorants and ducks, which benefit from the gulls' anti-predator responses.

[*Larus ichthyaetus*, Sivash, southern Ukraine. Photo: Valery D. Siokhin]

Gull colonies may be on the ground or in a more elevated position. Among the cliff-nesters, the largest colonies are formed by Black-legged Kittiwakes, and the noise emanating from them is a most characteristic and unforgettable sound as tens of thousands of birds utter their unmistakable call. Even in colonies, individual pairs defend a territory immediately around the nest. For kittiwakes, nesting on narrow cliff ledges, the territory size is determined by the size of the ledge. Moreover, whereas chicks of most gull species learn to recognize their parents' calls at about one week, when they begin to wander from the nest, voice recognition is less important for kittiwakes; the precarious nest-site prevents chicks from wandering.

[*Rissa tridactyla tridactyla*, Helgoland, Germany. Photo: Günter Ziesler]

to predator "swamping": the predators take a smaller proportion of the eggs or chicks, because these are available for a shorter time.

The relationship between breeding synchrony, predation and breeding success has been studied in a large number of gull species. In general, larger colonies are more synchronous up to a point, and have higher breeding success. There seems, however, to be a threshold of 100-300 pairs; above that, any increase in the number of pairs is not associated with an increase in breeding synchrony or reproductive success. It may be that social facilitation increases only up to a certain group size, and thereafter a rise in the number of birds does not lead to more social stimulation.

Early in the breeding cycle, gulls begin to gather at "clubs" on their nesting colonies, where they solicit for mates or re-establish pair-bonds. They gradually spread out over the colony to delimit and defend nesting territories. Unmated males defend territories and court potential mates, while mated pairs defend the territory together and engage in pair-bond maintenance. During this phase, gulls use long calls, mew calls or crooning to attract mates, and mew calls and head-toss calls to continue pair-bonding. They use aggressive long calls and ground and aerial attacks to repel intruders of both sexes.

Gulls are very vocal at all phases of the breeding cycle, from territory acquisition to the fledging of chicks. They call when flying, before landing, on landing, and when on their territories. Whereas almost all gull colonies are noisy, some, including those of Franklin's and Laughing Gulls, are particularly so. There are two exceptions: Bonaparte's Gulls, which nest in very loose colonies, and Andean Gulls, which nest in small colonies at remote Andean ponds, are relatively silent as part of their nest defence.

The visual displays of gulls are usually accompanied by calls. They are quite stereotyped, and are recognizable from species to species. The most frequent display observed at breeding colonies is the "Long Call", which is given in a variety of contexts, both from the ground and while flying. The bird raises its head above the horizontal, and gradually lowers it while giving a series of long notes. The long call is frequently followed by a series of "Head-tosses", when the gull flings its head up over its back while giving a plaintive note.

Once pairs have formed, they may spend hours every day engaging in displays and calling, alternating with courtship feeding. Within a few days, the pair begins to select a nest-site, and each partner shows the other its choice with a "Choking" display that becomes more intense and more frequent as the time of nest building approaches. The gull presses its cheek towards the ground until it nearly touches it, and then utters a low sound as if it were choking or trying to regurgitate; all the while the bird moves rhythmically up and down, with breast feathers puffed out and neck withdrawn. Each member of the pair "Chokes" at its chosen spot, and then watches while its partner "Chokes" at its favoured nest-site; this continues until the two agree on the same site, and both "Choke" there in tandem. "Choking" displays can go on for several minutes.

Nest building is an integral part of pair formation and pair maintenance for some species, and is less important for others, depending upon physical constraints. All gulls construct a nest, and use vegetation to form a nest cup. Typical nests are large bulky structures of grass and herbaceous vegetation plucked from the area around the nest. Marsh-nesting species begin building soon after selecting territories, because they must construct a nest platform for displaying to potential mates and for re-establishment of pair-bonds. For these species, such as Franklin's and Brown-hooded Gulls, both sexes gather material, but the male may make more trips while the female does more of the arranging of material. For species that nest in tidal marshes, such as the Laughing Gull and some Common Black-headed Gulls, nest construction is essential to provide a dry place for breeding activities. For cliff-nesting species such as the kittiwakes, for which nest material is very limited, provisioning of material plays an important role in maintaining the pair-bond.

Males of most gull species courtship-feed their mates in the period prior to egg-laying, although to a lesser degree than in the

terns. Nonetheless, courtship feeding can provide the female with a substantial percentage of her energy requirements. Courtship feeding is usually associated with copulation.

Over a period of 7-10 days before egg-laying, pairs engage in copulation, which increases in frequency and duration as the time of laying approaches. Copulation is always accompanied by a staccato, repetitive copulation call and by "Wing-flagging", which is visible far across the colony and leads to contagious copulation by neighbouring pairs. This social facilitation is believed to lead to greater breeding synchrony both within subcolonies and within the colony as a whole. Bouts of copulation are longer and more frequent in the early morning than later in the day.

Since, in many species of gulls, both members of the pair are on their territory for much of the day, territorial defence is strong, and territories tend to be relatively large during courtship and the pre-incubation period. Intruders have a difficult time inserting themselves into occupied parts of the colony. Species that nest on the ground or on water can determine territory boundaries based on social interactions. On water, however, emergent vegetation is required for anchoring the nest, and this limits the placement of nests as well as the size of territories. For species that nest on cliff ledges or in trees, territory size is often determined by the size of the ledge, the closeness of trees, or the space on the tree that can support a gull nest.

Most gulls have a clutch size of three eggs, although some, such as Hartlaub's, Black-billed and Silver Gulls and the kittiwakes, usually lay only two, and Swallow-tailed Gulls lay only one. Eggs are normally laid at two-day intervals. Generally, the first and second eggs are similar in size and shape, while third eggs are usually smaller, in particular narrower, and sometimes distinctly paler. Most gulls' eggs are pale tan to dark brown, or an olive greenish, with dark brown to black splotches and scrawls. They are thus camouflaged, and difficult to see on most surfaces, which effectively reduces predation, especially in species where nests are not close together. Some predators, however, including human beings, can form a "search image" and readily find the cryptic eggs.

Virtually all species raise only a single brood, although most will lay at least one replacement clutch, and sometimes more, if they lose their eggs or chicks. In general, replacement clutches average about one egg fewer than the initial clutch.

Both sexes incubate. For most species the incubation period averages 22-26 days, or more if the birds are frequently disturbed. The territory is defended by both members of the pair during this period, but its size may shrink slightly because the first priority is protecting the eggs. Some species, particularly those that nest densely, use a staccato "gakkering" call to defend the nest against neighbours and intruders, including those of other species: a bird remains sitting, stretches its neck forward, and opens its bill, sometimes "gakkering" for several minutes. Incubation sometimes begins with the first egg, but becomes continuous only after the second egg is laid. In most species, incubation bouts usually range from one to four hours during daylight, with one member of the pair sitting throughout the night, when the other normally also stays on the territory.

A clutch of three eggs normally takes 4-6 days to complete, while the hatching interval is usually under two days. The first two chicks hatch within a few hours of one another, but the third may hatch a day or two later, giving it a distinct disadvantage. The cryptic downy chicks are usually pale tan or greyish, variously spotted or streaked with small, discrete or irregular blackish marks. They are brooded until 1-2 weeks old, and are usually guarded by one or both parents until they fledge.

Both parents feed the chicks. During the first week the male provides more food, while the female remains on the territory and broods and guards the chicks. After the first week or two, the parents take turns in foraging and chick-guarding. Unless disturbed by storms, flooding or human beings, chicks remain near the nest-site throughout the fledging period. At this time, territories may be enlarged slightly, encompassing space abandoned by unsuccessful pairs or currently unoccupied. The larger territories provide room for the young to walk about without clashing with neighbours. Territorial conflicts can result in injury or death, quite apart from cannibalistic attacks. In some species, for example Black-billed and Western Gulls, the older chicks form a loose crèche when the parents are away feeding.

Gull colonies are usually noisy places, but those of the Andean Gull are an exception. This species breeds in small colonies at remote lakes in the Altiplano of the Andes, at altitudes from 4000 m to above 5000 m, where it nests on small islets or builds a floating nest anchored to emergent vegetation. At the approach of an intruder, the nesting gulls, rather than giving alarm calls and actively defending the colony by communal mobbing, all leave the area in complete silence; this presumably makes it difficult for the colony to be located by a predator in the vast and rather uniform, barren landscape, and would appear to have evolved as an efficient anti-predator strategy in an area which has long been occupied by man.

[*Larus serranus*, Lauca National Park, north Chile. Photo: Günter Ziesler]

The inland montane deserts of north Chile where the Grey Gull breeds are so barren and arid that the birds have to visit the coast every day to feed, a round trip of up to 200 km. The non-incubating mates leave after dark and return just before dawn. They feed along sandy beaches, mainly on mole crabs (Eremita analoga)*, which they obtain during a brief period before and after low tide, by probing the wet sand behind retreating waves. They make one feeding trip daily, bringing back mostly fish to feed to the chicks. As soon as the young fledge, at around 40 days, they, too, fly to the coast. Like several other seabirds, the Grey Gull may not breed in years when its food sources and foraging efficiency are adversely affected by El Niño.*

[*Larus modestus*, near La Serena, Chile. Photo: Günter Ziesler]

Chicks learn to recognize their parents' calls at about the time they begin to wander from the nest. In ground-nesting gulls this is by 6-8 days of age, although in marsh-nesting Franklin's Gulls it is not apparent at 15 days of age, and in the cliff-nesting kittiwakes not even by 28 days of age. In the last two cases, however, early recognition is not necessary, since chicks do not wander from the nest: kittiwakes because they nest on cliff ledges, and Franklin's because the nest is surrounded by water.

When disturbed by floods or human activities, gulls may move their chicks to higher ground or to other places where there is more vegetation and less disturbance. For example, if floods threaten Black-billed Gulls nesting on ephemeral islands in the middle of potentially raging rivers, the adults move their chicks to higher ground or to other islands soon after they hatch; and Herring and Laughing Gulls nesting in salt-marshes move their chicks to higher ground during excessively high storm tides. By contrast, Western Gulls exposed to excessive heat will move their chicks closer to water.

The fledging period for gulls ranges from four to seven weeks, depending on body size. For most species, at least one parent remains at the nest to protect the chicks from predators or conspecifics until they are able to fly. Young gulls usually spend a week or two learning to fly before leaving their nest-site, although they may exercise their wings much earlier. Once capable of flying, some species leave the colony and disperse or begin migration. Others, such as Herring Gulls, may continue to occupy the colony site as a family for up to 45 days, while the young learn to forage; during this time, the young may return to the territory only once a day, and the parents continue to feed them, either at the nest-site or in the vicinity of the colony. In Western Gulls, too, post-fledging care may extend beyond a month after the young can fly. The full extent of post-fledging parental care has not been established for most gulls, but for some it clearly continues for several weeks after fledging.

Parental effort has been examined for a number of species, and in general, averaged over the entire season, the two sexes contribute an approximately equal effort. Males often provide more of the initial territory defence than females, perform all of the courtship feeding, and may provide the bulk of territorial defence during incubation, as occurs in Western and Ring-billed Gulls. Females sometimes undertake more of the incubation and chick defence than males. In territorial clashes, if both sexes are present on the territory, males tend to defend against males and females against females. When the time and energy devoted to territory defence, incubation, chick feeding and chick protection are examined over the entire breeding cycle, however, the sexes generally have equal investment.

Herring Gull pairs with equal parental investment during incubation raise more young that those with unequal investment. Contrary to some sociobiological theories, equal investment and increased productivity may result when each pair member is trying to maximize rather than minimize investment, resulting in the chicks receiving maximum care. Species such as gulls, for which food is often abundant, have sufficient time to devote to breeding activities, and conflict between pair members over parental duties may be minimal compared with that of some other seabirds which travel many hundreds of kilometres to find food.

Gulls have provided important models for studying the role of conflict between parents, between parents and young, and between siblings. Their abundance, accessibility and density make it possible to follow investment, behaviour and conflicts, and the breeding cycle is short enough that both parent and young gulls can easily be marked and followed.

Conflict between parents over breeding activities clearly occurs: sometimes both parents attempt to incubate at once, or to feed the chicks at the same time, or both attack an intruder. This is contrary to traditional sociobiological theories, which state that each parent should minimize its own effort so that the other parent contributes more than 50% to current reproduction, thereby saving energy and reducing its own vulnerability, so as to protect its future breeding efforts. As mentioned above, however, when breeding activities and investments are considered for the entire breeding cycle, the sexes generally have equal investment. Moreover, Herring Gull pairs that have a relatively equal distri-

For a week to 10 days before egg-laying, gulls engage in copulation, the frequency and duration of which increase as the time of laying approaches. Bouts of copulation are also more frequent and of longer duration in the early morning than later in the day. The act of copulation itself is frequently preceded by the male courtship-feeding his mate; it is always accompanied by a repetitive copulation call, a series of short, staccato "ka-ka-ka-ka" notes, and by "Wing-flagging". The latter action, which can be seen by other gulls across the colony, appears to stimulate neighbouring pairs to copulate. This social facilitation may lead to increased synchrony in the breeding timetable within subcolonies, and also within the colony as a whole, but this is not always borne out in studies. In southern South America, for example, the Dolphin Gull nests in small, dense colonies, generally of up to 25 pairs, but the breeding timetable within colonies has been found to be highly asynchronous.

[*Leucophaeus scoresbii*, Patagonia. Photo: Jen & Des Bartlett/ Bruce Coleman]

The Black-billed Gull of New Zealand breeds almost solely inland, on rocky islands in fast-flowing rivers and along lake shores, sometimes near colonies of Kelp Gulls (Larus dominicanus). *Such habitats may on occasion be threatened by sudden raging floodwaters, which the gulls counter by moving their chicks to higher ground. The normal gull clutch size is three eggs, although the Swallow-tailed Gull* (Creagrus furcatus) *lays only one egg and a few species, including the Black-billed, usually two. The eggs are a light tan to dark brown or olive green, with darker splotches and scrawls, a camouflage which helps to reduce predation, especially where nests are widely spaced.*

bution of incubation and brooding effort between the sexes raise more young than pairs with an unequal distribution of such duties. Minimizing short-term parental investment is clearly disadvantageous.

In theory, parent-young conflict usually relates to chicks seeking more and longer parental care, while parents attempt to protect their own survival and future investment by limiting the number of feeding trips and shortening the duration of care. Evidence for this conflict comes from observations of the squabbles that occur at the nest-site when chicks beg for food from parents that do not feed them. In California Gulls, the amount of time parents withheld food from offspring increased through the nestling period, but older, presumably more experienced, parents were less likely than younger ones to withhold food and they offered longer periods of parental care. In some species, such as Herring Gulls, this conflict may be as to when, rather than whether, to provide care. Moreover, Herring Gull parents remain on the territory long after the young fledge, and feed them as soon as they return. Thus, gull studies partly refute the traditional understanding of parent-young conflict.

There may be conflict among siblings. Although siblicide is rare, older chicks beg more vigorously and may outcompete late-hatched siblings for food, thereby hastening the latter's demise. At least in Herring Gulls, parents may compensate, with each one providing food almost simultaneously in different parts of the territory, allowing all chicks to obtain food.

Conflicts between different generations have also been described, and not only within a family. Gulls may either adopt strange chicks that wander into their territory or they may attack and kill them. Adoptions have been reported for several species, including Western, Herring, Ring-billed, Mew, Lesser Black-backed, Laughing, Franklin's and Sabine's Gulls, although it may occur in most ground-nesting gulls with chicks that can move between nests. Adoptions have even been reported in a Black-legged Kittiwake colony where movement between nests was possible, although only 8% of the chicks that moved were adopted. When examining this phenomenon, it is important to be certain that events occur naturally, rather than as a result of human interference. For example, adoptions detected among Franklin's Gulls were due mainly to human disturbance causing chicks to swim from their nests; in normal circumstances, young Franklin's Gulls never leave their floating nest platforms, and adoptions would not occur.

Since recognition both of chicks by parents and of parents by chicks becomes well developed in ground-nesting gulls after several days, it is not clear why adoptions occur, as parents will then be investing time and energy in offspring that are not their own. Hypotheses proposed to explain why adoptions occur regularly at some colonies include reciprocal or weak altruism, mistakes by parents in high-density sites, and that adoption is a chick strategy to increase its own survival. Chicks that are not receiving adequate parental care may abandon their nests and seek care from other, unrelated adults. Their behaviour is aimed at promoting adoption by thwarting aggression from both adults and future "siblings". Chicks seek adoption in broods with slightly younger and smaller chicks.

In several species, 20-30% of the chicks that abandoned their natal territories were successfully adopted by foster parents, while a similar proportion were killed by conspecific adults. The adopted chicks, however, were often fed at lower rates than the adult's own offspring. Considerable research is needed to establish the role of adoptions in the reproductive strategies of different species of gulls.

Reproductive success usually increases over the first few years of breeding, and remains relatively high, decreasing only in very old birds. This basic pattern has been observed for all species for which there are adequate data, including Black-legged Kittiwakes and Herring, Glaucous-winged, Red-billed and California Gulls. Age-related increases in fledging success are correlated with increased adult mortality, at least for California Gulls.

Measures of reproductive success for gulls have traditionally included egg size, clutch size, hatching rates, fledging rates (young per pair), chick weight and, more recently, recruitment rates to the breeding population. Gulls normally lay two or three

Typical gull nests are bulky structures of grass and herbaceous vegetation gathered from the immediate surroundings. In marsh-nesting species, which have to construct a nest platform for display purposes, building starts soon after territory selection, both sexes gathering material, but the female doing more of the arranging. For those species nesting in tidal marshes, which include some Common Black-headed Gulls (Larus ridibundus) *and Laughing Gulls* (Larus atricilla), *a solid nest construction is needed to provide a dry site for breeding; for cliff-nesting species such as kittiwakes* (Rissa), *the provisioning of nest material, which is limited in availability, is important in pair-bond maintenance. Franklin's Gull breeds in exceptionally noisy colonies, containing up to 150,000 pairs, exclusively at inland lakes and marshes. Although some of its nests may be free-floating, most are placed on emergent vegetation over water about 1 m deep, and require daily maintenance to prevent them from sinking. The chicks normally remain on their floating nest platforms unless seriously threatened, when they may swim into nearby reeds. During incubation, some gulls, but particularly those that nest at high densities, utter a staccato threat call when confronted by intruders, including those of other species: with neck stretched forward, they give a "gakkering" call, which can persist for some minutes.*

[*Larus pipixcan*, Kaysville, Utah, USA. Photo: R. J. Erwin/DRK]

Incubation is performed by both sexes, and for most species lasts an average of 22-26 days, being extended if there are frequent disturbances during this period. At the same time both sexes defend the territory, but their main priority is to protect the eggs; the territory size may therefore be somewhat reduced during the incubation period. During the day an incubation stint generally lasts for one to four hours; at night, one member of the pair sits throughout, while its mate normally remains close by on the territory.

[*Xema sabini sabini*, Rowley Island, Foxe Basin, Northwest Territories, Canada. Photo: Jan van de Kam/ Bruce Coleman]

eggs, and fledging rates for most of those that fledge any young range from one to two chicks. The availability of supplementary food from refuse has enabled Herring Gulls successfully to rear all three chicks, and no doubt contributed to their population explosion. It is becoming clear, however, that survival to fledging or independence is not always predictive of recruitment into the breeding population. This is partly because other factors have a major influence on the survival of young after they leave the breeding grounds. At least in Western Gulls, recruitment into the breeding population is more reliably predicted by survival of young to one year of age.

Several long-term studies have followed individuals throughout their reproductive years. In a 29-year study, 81 male and 66 female Red-billed Gulls showed considerable variation in the total numbers of young raised to fledging. Depending on the year cohort, 45-100% of the male and 66-100% of the female fledglings died before they could breed; and, of those that did return to breed, nearly 40% fledged no young in their lifetime. Thus, during their entire reproductive careers, only 17% of breeding males and 24% of females produced young that successfully bred in the colony. Frequency of breeding, longevity and laying date were the most important sources of variation in lifetime productivity. Gulls laying earlier in the season were more successful.

Current reproductive effort may affect future survival. For example, in California Gulls, increasing effort with age was associated with reduced survivorship. Reproductively induced mortality resulted from the cumulative effects over the entire breeding season. Younger adults fledged fewer offspring but had high survival rates, while old gulls tended to fledge more offspring but had low survival. Old gulls that fledged few offspring, however, survived as well as young gulls.

Movements

Typically, gulls leave the breeding grounds following the fledging of their chicks, remain with the juveniles for a few weeks, and then migrate or disperse for a variable distance to wintering grounds.

Most gull species are migratory, moving to warmer regions for the winter. Movement patterns vary with age, young often moving farther than adults. Migration of large flocks usually occurs at night, although gulls will also migrate during the early morning and late afternoon, when hundreds or thousands may be seen streaming over land or along coasts or waterways.

Many species, including the Black-legged Kittiwake and Sabine's, Laughing, Common Black-headed and Brown-headed Gulls, show directed migration to lower latitudes for the winter. Remarkably, however, some of the high latitude species do not show this trend. Ivory, Iceland and Glaucous Gulls disperse only to the edge of the ice and open water. Ross's Gull migrates in large numbers eastwards past Point Barrow, Alaska, in autumn, and, since no return spring migration has been documented, it may have a complete circumpolar movement or may return far from shore over the ice. The Mediterranean Gull likewise migrates across longitudes, mainly from the Black Sea to the western Mediterranean.

Some gulls are long distance migrants, flying many thousands of kilometres from Arctic or north temperate breeding grounds to South America, Africa or southern Asia. The small gulls migrate longer distances than the large gulls, several being transequatorial migrants. Franklin's Gull migrates farther than any other, some reaching extreme southern South America from breeding grounds in Canada. Other small gulls, such as Sabine's and Common Black-headed, also have long transequatorial migrations. The small gulls that breed in interior South America and Africa, however, do not migrate so far, and some of their movements are nomadic rather than truly migratory. Brown-hooded Gulls leave their breeding marshes of northern Argentina and roam the coasts of Argentina and Brazil, but do not show directed migration towards the tropics. Similarly, Black-billed Gulls breeding on riverine shingle in New Zealand move only to the coasts during winter. Many Heermann's Gulls disperse northwards along the Pacific coast after breeding.

In three-egg clutches, the first two chicks hatch within a few hours of one another; the third may hatch up to 48 hours later, and so starts off with a distinct size disadvantage. The downy chicks of gulls are usually pale grey or tan brown, with irregular dark markings on the dorsal surface, giving them very good camouflage. They are fed by both parents, the male providing more food during the first week, while the female broods and guards the chicks. The large red spot on the mandible of many large white-headed gulls, such as the Great Black-backed Gull, serves as a stimulus to the young chicks to initiate feeding.

[*Larus marinus*, Unst, Shetland, Scotland. Photo: C. Reddick/Aquila]

Many large species of temperate and subarctic regions migrate only a few hundred kilometres, and others simply disperse along nearby coasts to favourable feeding grounds. Thus, Herring, Ring-billed and California Gulls spread out along the coasts of North America. In the Old World, however, many Herring Gulls breeding in the Baltic winter in the southern North Sea and Britain, while Baltic Lesser Black-backed Gulls migrate to the Black Sea and the eastern Mediterranean, many even continuing into Africa. Some species, such as the Western Gull, are essentially sedentary, remaining in nearby coastal areas or moving south only short distances in the non-breeding season.

The smaller species usually migrate in large, dense flocks, while this is less true for the larger gulls. Huge aggregations sometimes remain intact during the winter. In 1994, flocks of up to half a million Franklin's Gulls migrated through the southern USA, and up to a million have been observed together in Peru in winter.

Vagrancy among gulls is by no means uncommon. For instance, Nearctic species occur annually in western Europe, and of particular interest is the Ring-billed Gull. This species was unknown in Britain until 1973, when it was reported in Wales; subsequently, the number of annual records increased dramatically, and this gull has become regular in many parts of Britain and can be seen at all times of the year. These events are no doubt linked to the species' huge increase in eastern North America. Ring-billed Gulls have now been recorded in many countries of Europe, as far east as Sweden and Poland, and frequently south to Spain.

Relationship with Man

Unlike many seabirds, most gulls spend their entire lives along coasts, and some breed inland. Gulls have therefore been an integral part of the natural world around coastal human settlements, establishing a level of commensalism, and they have been exploited for thousands of years.

Throughout history, gulls have provided man with food in the form of eggs, chicks, and even adults, and their feathers have been used in the fashion industry. Since gulls are primarily coastal, the first sighting of flocks of gulls was used by ancient mariners as a welcome sign that land was near. Fishermen today recognize that flocks of gulls can help them locate fish.

Bird eggs can provide an important and free, although seasonal, source of food for man. Collecting eggs for food, or "egging", has a long and continuous history in Europe, the tropics, the Arctic, and other parts of the world. In many places, colonies of gulls and other seabirds were "managed". Particular colonies or parts of them belonged to specific families or clans, and individuals and their descendants were responsible for maintaining the colony for the use of future generations. Eggs were collected only early in the season, and pairs were then allowed to raise young. In other cases, only a part of the colony was egged each year, and the areas egged varied from year to year. In some cultures, elaborate records were kept of the areas egged, the timing of egging, and the number of eggs taken. At Ravenglass in northwest England, records of continuous, yearly egging date back to the 1600's; this colony of Common Black-headed Gulls had an annual yield of 30,000 eggs, and was protected from overexploitation by careful local regulation. There are similar histories of egging of Black-legged Kittiwake colonies in many regions, although often only the lower areas of cliff were accessible. Even today, gull and other seabird eggs remain an important food source for many people.

In parts of Europe, gulls were often featured at banquets. During the seventeenth century chicks were collected soon after hatching, and were fattened in gull houses on country estates for special feasts. Fashionable ladies sent gulls as gifts to neighbours, much as we might send cakes or flowers today.

The early European settlers in North America brought with them a predilection for bird eggs. Unlike those in Europe and the Arctic, however, North American colonies were not owned by particular families, protection was non-existent, and overexploitation occurred. By the nineteenth century gull numbers

had decreased along the Atlantic coast, but legal protection in the early twentieth century, and artificial sources of food, dramatically reversed this process (see Status and Conservation).

Recently, some species have become pests in places. Gulls have caused problems at landfills and airports, and in agricultural areas or suburban communities, where they occur in high concentrations. Gull control has become a controversial issue, involving a mixture of scientific information, conservationists' pleas, public perception, political pressures, and legal constraints.

Most major airports located in coastal areas experience problems with gulls, particularly during migration, involving species such as Ring-billed, Herring and Laughing Gulls in North America, Silver Gulls in Australia, and Black-headed and Mew Gulls in Europe. Elaborate control measures have been introduced to decrease the likelihood of collisions between aeroplanes and birds, referred to as bird strikes, most of which occur near airports while planes are landing or taking off. Control measures include scaring with shell crackers, bangers, and blank and live artillery shells; playing recordings of gull distress calls; flying captive falcons; installing monofilament lines over loafing areas; preventing nesting near airports; and shooting of adults. One effective method of preventing accidents on take-off or landing is to use vehicles to clear gulls off the runway before their use by aircraft. In 1979, Laughing Gulls began breeding in a marsh at the end of a runway at J. F. Kennedy Airport, New York, and this colony grew exponentially to thousands of pairs; from the early 1990's thousands of the gulls and other species were shot at the airport, despite substantial public objection.

In North America, the Great Lakes' Ring-billed Gull population has increased dramatically, from 27,000 breeding pairs in the 1940's and 1950's to 710,000 pairs in 1990. This increase has been associated with concerns for airline flight safety, human health, and agricultural and horticultural damage. Gulls nest on urban roofs and sometimes interfere with industrial operations, while expanding populations may preempt colony sites of other species such as Common Terns. Control of Ring-billed Gulls has involved scaring them, excluding gulls from areas by wires or other devices, removing or modifying attractive habitat, and reducing or preventing their reproduction. Yet the gull numbers are still growing. Even with constant vigilance, humans have been able to halt the population explosions only so long as the control measures continue.

Similar problems are caused by Glaucous-winged, Herring, Yellow-legged, Common Black-headed and Silver Gulls, which have adapted to urban environments and learned to take advantage of food at landfills and from marine processing activities. They have all increased dramatically this century. While the problems are acute and potentially lethal around airports, gulls are no less of a nuisance in agricultural, suburban and urban environments. In Europe, the expansion of Herring Gulls has provided additional problems for fish and shellfish aquaculture, and has been linked with the possible spread of harmful pathogens.

Gulls also compete directly or indirectly with other native species for breeding places, and they prey on other birds. When their populations were in balance with those of other species, their habits were not harmful. With increased numbers and consequent range expansions, however, they now compete directly with smaller species, which in some cases have been extirpated from their traditional nesting islands by large gulls. Management of gulls can be a major problem at some nature reserves. Attempts have therefore been made to control their populations or even eliminate certain colonies to facilitate the recovery of terns and other seabirds. In the north-eastern USA, for example, some efforts have been made to control populations of Herring and Great Black-backed Gulls, so that Common and Roseate Terns (*Sterna dougallii*) can re-establish nesting on some islands.

On a more positive note, gulls are now serving man as bioindicators of environmental problems. The feminization of embryos as a result of DDT exposure was first noted in gulls in the early 1980's, and was our first warning of the subtle but pervasive effects of environmental oestrogens or endocrine disruptors, now being examined as a cause of widespread developmental and reproductive problems in vertebrates.

In North America, colonial fish-eating seabirds such as Herring Gulls are being used to study the effects of chronic exposure to complex mixtures of persistent environmental contaminants,

Young gulls are guarded by one or both of their parents throughout the fledging period, the family remaining at or near the nest-site. The threat of predators is ever present, and in many gull colonies conspecifics will attack and kill young of other pairs, especially if chicks wander out of their parents' individual territory. Here, an Andean Gull on its remote high altitude breeding lake is giving a threat display and call to other Andean Gulls flying past. As a further safeguard to protect their chicks, many breeding gulls will enlarge their territory during the fledging period, enabling chicks to walk around without risk of attack from neighbours.

In parts of the Arctic, the Ivory Gull breeds on inaccessible cliffs. The chicks take at least four to five weeks to fledge, and, as with most gulls, at least one parent stays with them until they can fly sufficiently well to have a reasonably good chance of surviving on their own. Unlike most gulls, in which juveniles and early immatures are heavily patterned with dark markings, juvenile Ivory Gulls look very white, having only small, sparse blackish spots, a "dirty" face and a narrow blackish tail band. This most beautiful of gulls spends its entire life in Arctic waters, and is very rarely seen south of the ice limit.

[*Pagophila eburnea*, Spitsbergen, Svalbard. Photo: Rinie van Meurs/ Bruce Coleman]

particularly the lipophilic chlorinated hydrocarbons such as DDT and PCB's, within the entire Great Lakes ecosystem. Birds are being used as models to determine large-scale environmental effects, and in places contaminants have been suspected to have significant effects on gull populations (see Status and Conservation). The capacity of gulls to provide early warning of environmental problems is particularly important when indicators are required to assess ecosystem health.

Status and Conservation

The world populations of gull species range from a few hundred pairs to more than a million pairs. Ironically, some gulls with global populations of under 50,000 pairs, such as the Yellow-footed Gull (*Larus livens*) and the Western Gull, are considered serious pests and, paradoxically, attempts may be made to reduce their numbers in order to protect other species on which they prey or with which they compete, even when the latter are much more abundant than the gulls themselves.

Several species have limited or highly restricted breeding distributions, but, for the most part, gulls have wide ranges and enjoy stable or even increasing populations. Because many gulls breed in places which are readily accessible to humans, their nesting colonies are vulnerable to direct human exploitation, disturbance and habitat loss. Nonetheless, only five species are currently listed as globally threatened. These are Olrog's and the Lava Gulls in the Neotropics, the White-eyed Gull in the Middle East, Saunders's Gull (*Larus saundersi*) of eastern China, and the Nearctic Red-legged Kittiwake (*Rissa brevirostris*).

Olrog's Gull was recognized as a species distinct from the Band-tailed Gull only in 1958, and it was not named until 1977, at which time only one colony was known. With a very limited breeding range, restricted to the Argentine coast, its numbers do not exceed 1400 pairs, and the few known colonies suffer disturbance, destruction and egg-collecting for food. It is certainly threatened.

The Lava Gull has the smallest world population of any gull, with only about 300-400 pairs. It is currently well protected, but, with increasing human colonization of the Galapagos, the National Park itself may be in jeopardy and the gull's future is by no means assured.

The White-eyed Gull breeds only in the Gulf of Aden and on Red Sea islands, with a total population probably of around 4000-5000 pairs. It is at risk from the effects of oil pollution and various human pressures, including disturbance, the taking of eggs and young from breeding colonies, and development of its nesting habitat.

Saunders's Gull similarly has a limited distribution, on the east coast of China, where about 3000 pairs survive. Having already lost most of its salt-marsh breeding habitat, it is now Endangered owing to further coastal development, along with disturbance, hunting and pollution. All seven known colony sites are either being developed or are planned for development for agriculture or aquaculture. Unfortunately, it is not treated as an endangered species by the Chinese authorities, yet protection of its breeding grounds is of critical importance.

The seven known colonies of the Red-legged Kittiwake are all in the Bering Sea. Although there has been some increase in numbers at some of these in the last two decades, the two colonies in the Pribilof Islands have experienced a 50% decline, apparently a result of food shortage. The species is considered Vulnerable.

The Relict Gull, which breeds at a few sites in Kazakhstan, Russia, Mongolia and China, is one of three near-threatened gull species. Its world population is uncertain, but may perhaps be no more than 2000 pairs, although the existence of as yet undiscovered breeding sites is possible. The Relict Gull has declined seriously in Kazakhstan, and its nesting colony on Lake Alakol is nearly gone. The cause of this is obscure, for this remote species has rarely been studied. Nevertheless, its eggs and chicks are known to suffer serious predation from Yellow-legged Gulls, and the species is extraordinarily susceptible to adverse weather and to human and other disturbances, both of which factors can lead to the elimination of entire colonies.

Saunders's Gull is restricted as a breeding species to the east coast of China, where most of its salt-marsh breeding habitat has already been destroyed. Development is currently taking place at, or is planned for, the very few remaining colony sites, and disturbance, hunting and pollution are additional threats to its survival. It is now classified as Endangered, with only some 3000 pairs left. Protection of its breeding grounds is vital.

[*Larus saundersi*, Deep Bay, Hong Kong. Photo: Sue Earle/ Planet Earth]

The other two near-threatened species are Heermann's Gull and the Pacific Gull. The former is still numerous, but 90% or more of all its pairs nest in a single colony on Mexico's Isla Rasa, in the northern Gulf of California. The Pacific Gull is Australia's only endemic gull, restricted to remote coasts and islands of the south, where it may now be subject to competition with the successful Kelp Gull, which has recently colonized this zone. Although still numerous and not listed as threatened, the Black-billed Gull, a New Zealand endemic which nests mainly on ephemeral river shingle bars, is vulnerable to a loss of habitat caused by invading exotic vegetation; it requires habitat management.

A recent, well documented conservation success story is that of Audouin's Gull, a species endemic to the Mediterranean zone. Very few breeding sites exist, and 90% of the total population breeds along the Spanish coast. Its colonies suffered serious disturbance from fishermen and visitors, and also from military activities, and, in view of the precarious situation, in 1987 the Spanish government initiated a co-ordinated conservation programme for the species. This involved constant protection of all the breeding colonies, as well as additional measures, such as the culling of Yellow-legged Gulls at two island sites and the elimination of rats from one of them, vegetation management at another site, the protection of some of the principal stopover sites, and thorough research of the parameters dictating the species' biology.

These measures have enabled a marked increase from the total of 800-1000 pairs estimated in 1966, when the species was considered one of the rarest of all gulls, to 15,600 pairs in 1993. Much of this overall increase is due to the growth of the colony at the Ebro Delta, which was first occupied only in 1981, but by 1995 had grown to hold 10,300 pairs, or 60% of the world population. Remarkably, this colony has increased at an annual average of 40%, and in the first years at a staggering average of 350%, figures which can only be explained by mass immigration of breeding birds in the early years, together with very high productivity of up to 2 chicks per pair per year.

The recent studies have shown that this species has a rather specialized diet, based on pelagic clupeid fish, for which it depends on the discards of the local fishing fleet. The existence of this highly predictable, superabundant source of food has certainly played a major part in the observed population growth, especially in the main colony at the Ebro Delta. Therefore, the maintenance of this food supply, coupled with continued protection of the breeding colonies, must be seen as key factors for the continuing survival of this species. Audouin's Gull is currently classified as Conservation Dependent, which means that due to specific active conservation measures it is not listed as a globally threatened species, but that it would be considered so if the measures were to cease.

Gulls have been profoundly influenced by man, perhaps more so than any other group of seabirds except for the auks and penguins, which were used extensively for their oil. Most of these influences have been negative, affecting reproductive success and population levels. The taking of gull eggs and whole birds for food and for the millinery trade had the potential to decimate their populations, but by the early twentieth century protective laws and treaties in several countries halted this wholesale exploitation.

Although eggers have lived in relative harmony with colonial-nesting gulls for most of the history of their co-existence, seabird populations began to suffer in the seventeenth and eighteenth centuries, because of expanding human populations and a breakdown in individual responsibility for colonies. Well into the nineteenth century, Black-legged Kittiwakes were still taken in large numbers by New England fishermen for food and bait; the small gulls were lured to boats by cod liver or other bait, and were captured by hand, nets or hooks. In England, Norway and other parts of Europe, Black-legged Kittiwakes were slaughtered on their breeding grounds. A century ago, harvesting at colonies in the USA was totally unregulated; during this period, the Great Black-backed Gull disappeared as a breeding bird from the Maine coast, breeding populations of Herring Gulls were pushed farther north, and Western Gull numbers on the Farallon Islands were seriously reduced.

During the late nineteenth century, bird hunting or market-gunning became serious business in North America, and birds were shot both for food and for fashion. White was a fashionable colour for the millinery trade, and the feathers of gulls, as well as those of herons, egrets and terns, were eagerly sought (see Volume 1, page 396). Entire wings of gulls often festooned fashionable hats in New England.

With the cessation of the killing of gulls for food and fashion, populations slowly began to rebound, and to reclaim former nesting grounds. Several species increased greatly, especially during the 1950's, and have become real or potential problems in some areas. In many cases, these increases are directly attributable to the availability of superabundant food at rubbish dumps, sewage outfalls, and fish-processing boats and factories.

The growth of gull populations during the present century is well known, most notably the enormous increases of Herring Gulls in both Europe and North America, of Silver Gulls in Australia, of Ring-billed Gulls in interior North America, and of Common Black-headed Gulls throughout Europe. Some of these expansions have slowed or stabilized, but through the 1980's Laughing Gulls have undergone almost a doubling of population levels in New Jersey, with a northward expansion into New York, where they bred prior to their elimination in the 1880's.

The Herring Gull provides an excellent example of a gull that has undergone extensive range expansions and a population explosion. At the end of the last century, the Herring Gull was largely a species of the low Arctic, in both the Western and the Eastern Hemispheres, with colonies in southern Canada and northern Europe. At the turn of the century, Herring Gulls began to increase in numbers and to spread southwards. From Canada, they spread into Maine, taking over islands once used by cormorants, puffins and terns; within a few years, small colonies grew into colonies of hundreds or thousands of pairs. In the first third of the twentieth century, they began to move into Massachusetts, taking over rocky and sandy islands used by terns and other species. Herring Gulls then moved into New York state, nesting on sandy beaches, grassy knolls and rocky islands, and by the 1950's they were firmly established in both Massachusetts and New York. The number of breeding pairs in New York peaked at about 25,000 in the mid-1980's, but has since decreased to about 15,000 pairs.

In 1948 the first Herring Gulls nested in New Jersey, and by the 1960's there were nearly 2000 pairs. With few sandy islands available for nesting, and no rocky islands, the gulls moved onto salt-marsh islands. By the 1980's there were nearly 4000 pairs in New Jersey, and they have displaced terns, skimmers and the smaller Laughing Gulls from many islands. Not only do they compete with these species for nesting places, but they also prey on their eggs and chicks. By the early 1990's there were nearly 6500 pairs nest-

Although a not unfamiliar bird in the Red Sea and the Gulf of Aden, the White-eyed Gull occurs nowhere else in the world. Its total population probably numbers about 4000-5000 pairs. Its status is not well known, but it is considered to be Vulnerable. It is at permanent risk from the effects of pollution by beached and floating oil, and is subject to various other human pressures, including increasing disturbance from tourism-related activities. Its colonies are robbed of both eggs and chicks, and its nesting habitats are threatened with further development.

[*Larus leucophthalmus*, Red Sea coast, Egypt. Photo: Oriol Alamany]

ing in New Jersey, but their numbers have now stabilized. Herring Gulls now nest regularly as far south as North Carolina.

Similar expansions can be described for Europe, where Herring Gulls have also displaced terns and the smaller Common Black-headed Gull from their nesting colonies. Attempts to control their numbers by shooting or harrassment, or by destroying their eggs have generally failed. Only the closure of rubbish dumps has been at all successful. Their populations do eventually stabilize, but at what is probably an artificially high level.

Not all of the commoner gulls, however, benefit from the activities of modern man. Franklin's Gull provides a good example of a gull that is particularly vulnerable to habitat loss. It requires large, undisturbed prairie marshes for nesting, and will not use small marshes that are near human activities. Its preferred sites are vulnerable to natural variations in the water-cycle, as well as to draining by man. When such marshes become unsuitable, whole colonies of upwards of 50,000 birds may leave in search of suitable sites. When these are not available, the gulls do not breed. A succession of drought years can result in a drastic reduction in the entire population of Franklin's Gull, to only 10% of its former level. Presumably, the drainage of large prairie marshes by man, added to the effects of natural drought cycles, could threaten this species. A similar plight exists for the Brown-hooded Gull in South America, and its populations should be monitored. Common Black-headed Gulls in Europe also use marshes traditionally, but they have adapted to nesting on dunes and beach habitats.

Contaminants are another cause of changes in gull populations. Although eggshell thinning was not a serious problem among gull populations in the 1960's, high levels of DDT have been responsible for the feminization of gull embryos, resulting in the inability of males to breed and contributing to skewed sex ratios.

On the Great Lakes, high mortality of embryos and chicks was reported among Herring Gulls as early as 1964, and by the early 1970's reproductive success was at best 10% of normal. Hatchlings exhibited impaired growth, congenital malformations, enlarged livers, and subcutaneous oedemata. Lower hatching rates appeared to be due to both intrinsic and extrinsic factors. Great Lakes parents did not incubate as effectively as gulls elsewhere; they applied less heat and were less attentive. The problem was a result both of egg quality and of parental quality: birds at "clean" sites elsewhere were unable to hatch "contaminated" eggs, and birds from "contaminated" colonies were unable to hatch eggs from "clean" colonies, where hatching rate was otherwise normal. Furthermore, more eggs disappeared from Great Lakes nests, a result of a lower level of parental attendance. The total organochlorine content of eggs from Lake Ontario was negatively correlated with the total time the eggs were attended.

This example clearly indicates that environmental pollutants can affect parental behaviour, embryo quality, and eventually reproductive success. It suggests that toxins, when present at lower levels, may also be affecting subtle aspects of behaviour and physiology that have a bearing on reproductive success. In the milieu of other factors that cause decreases in productivity, toxins may fail to be identified as a cause of reproductive problems until breeding success has decreased precipitously.

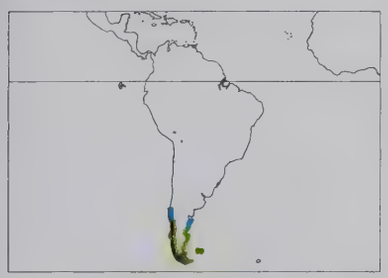
PLATE 50

inches 8
cm 20



Genus *LEUCOPHAEUS* Bruch, 1853

1. **Dolphin Gull**

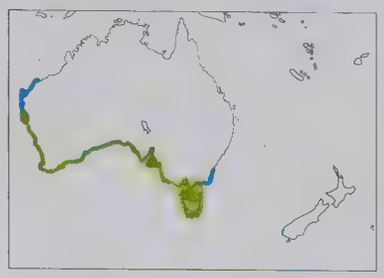
Leucophaeus scoresbii

French: Goéland de Scoresby **German**: Blutschnabelmöwe **Spanish**: Gaviota Patagona
Other common names: Scoresby's Gull

Taxonomy. *Larus Scoresbii* Traill, 1823, South Shetland Islands (probably = Falkland Islands).
Recently placed in *Larus* by many authors. Sometimes combined with *Larus pacificus* in genus *Gabianus* on basis of strongly hooked bill, but unique behaviour, plumage and chick pattern advocate placement in monospecific genus. Probably most closely related to *L. belcheri* and *L. atlanticus*, or to *L. heermanni*. Monotypic.
Distribution. S South America, from SC Chile (Chiloé I) and SC Argentina (Punta Tombo, Chubut) to Tierra del Fuego; also Falkland Is. Outside breeding season, occurs slightly further N on both mainland coasts.

Descriptive notes. 40-46 cm; 524 g; wingspan 104-110 cm. Uniquely plumaged gull, with uniform grey suffusion on head and underbody, dark mantle and black primaries, the latter with no white windows, and broad white triangular trailing edge to secondaries and inner primaries; tail white; heavy bill and shortish legs startlingly bright red; iris white, with conspicuous red orbital ring. Distinguished from *Larus belcheri*, which shares some of the same features, by smaller size, lack of black tail band, and noticeably different bare part colours. Non-breeding adult and second-winter bird have a darker grey-mottled hood. Juvenile unique among gulls, uniform dark brown with whitish belly and slaty-brown wing-coverts.
Habitat. Rocky coasts; breeds on low sea cliffs, sand or gravel beaches, marshy depressions, or headlands; often near fresh water or on ridges over sea (Falklands); usually found in vicinity of seabird colonies, marine mammals, slaughterhouses, sewers or farmyards. Non-breeders also frequent harbours.
Food and Feeding. Mainly carrion, offal, bird eggs and chicks; marine invertebrates, and other natural food. Scavenges around marine mammals for dead fish, placentae, and particularly faeces; natural foods are taken mostly early in season, before bird eggs available. Exploits human intrusion into seabird colonies by preying on unguarded eggs and chicks. Occasionally steals food being delivered to cormorant (*Phalacrocorax*) and penguin chicks, and pirates stolen penguin eggs from *Larus dominicanus*. Chicks fed mainly on fish scavenged from around penguin nests. Probes in seaweed; captures swarming beach flies; picks mussels, which are then dropped onto rocks. Does not frequent rubbish dumps, but sometimes feeds at sewage outlets.
Breeding. Attends colonies from Sept, laying sometimes in early Nov (Tierra del Fuego) or late Nov (Punta Tombo), but mostly in Dec; highly asynchronous. Changes location from year to year. Small, dense colonies (1-1·6 pairs/m²) of up to 25 pairs; maximum 210 pairs. Nest of kelp and vegetation, lined with grass; among boulders, or on bare volcanic rock (Punta Tombo), often sheltered by tussock grass. Lays 2-3 eggs (mean 1·9-2·0 Punta Tombo); incubation 24-27 days; tolerates intruders within 1 m of nest, but once flushed will attack; chick is the most boldly marked in any gull, with discrete black spots and streaks forming long bars from gape to below eye, on very pale ground colour; mean hatching weight 41 g; at 2-5 days follows parents from nest; older chicks may form crèche. Hatching success c. 50%; remainder of eggs presumably lost to predators.
Movements. Falklands population resident, but adults and young disperse widely around the islands. Populations from mainland South America move N, Chilean birds as far as Santa María I; Punta Tombo birds attend sea lion colonies 200 km to N, on Valdés Peninsula.
Status and Conservation. Not globally threatened. Many small colonies on South American coast, but size of total population unknown, although probably in low 10,000's. Species considered common in S Chile and on much of Tierra del Fuego. Most Patagonian colonies support fewer than 25 pairs (maximum 210 pairs); Punta Tombo colony holds only 17-24 pairs. In Falklands 85% of colonies contain fewer than 100 pairs, and overall population estimated at only c. 1000 pairs.
Bibliography. Blake (1977), Canevari *et al.* (1991), Castellanos (1935), Cawkill & Hamilton (1961), Clark (1986), Croxall, McInnes & Prince (1984), Devillers (1977b), Hellmayr & Conover (1948), Humphrey *et al.* (1970), Johnson (1967), Kury & Gochfeld (1975), Murphy (1936), Meyer de Schauensee (1982), Moynihan (1962), Olrog (1984), de la Peña (1992), Pettingill (1960), Philippi *et al.* (1954), Reynolds (1935), Woods (1988), Yorio *et al.* (1994), Zapata (1965, 1967).

Genus *LARUS* Linnaeus, 1758



2. **Pacific Gull**

Larus pacificus

French: Goéland austral **German**: Dickschnabelmöwe **Spanish**: Gaviota Tasmania
Other common names: Large-billed/Australian Gull

Taxonomy. *Larus pacificus* Latham, 1801, New South Wales.
Often placed in separate genus *Gabianus*, either alone or with *Leucophaeus scoresbii*. Considered monotypic by some authors. Two subspecies currently recognized.

Subspecies and Distribution.
L. p. georgii P. P. King, 1827 - Western Australia (Shark Bay) S and E to South Australia (Kangaroo I).
L. p. pacificus Latham, 1801 - Tasmania and Victoria; post-breeding visitor to New South Wales, rarely N to Queensland.

Descriptive notes. 58-65 cm; 900-1185 g; wingspan 137-157 cm. White head and underbody, with blackish mantle and wings, the latter with white trailing edge but lacking white windows on primaries; tail white with narrow black subterminal band; bill very deep and heavy (the heaviest of any gull), yellow, with red spot at tip; nostrils oval rather than slit-like; legs and feet yellowish. Eyes whitish, with orbital ring pinkish or yellowish. Larger than *L. dominicanus*, from which it differs also in darker mantle, black tail band, and heavier bill. Immature paler below and on rump. Juvenile dark brown, with dark bare parts. Races differ minimally.
Habitat. Coastal; rarely occurs inland. Breeds on elevated offshore islands; rarely on headlands in SE of range.
Food and Feeding. Fish, squid, and intertidal molluscs, echinoderms and crabs; fish offal, carrion and refuse; eats many gastropods (*Turbo undulatus*). At colony on Green I (Tasmania), feeds mainly on crabs (*Ovalipes australiensis*, *Paragrapsus gaimardii*) and chitons, as well as fish waste. Takes bird eggs and young, and occasionally adult birds, e.g. White-faced Storm-petrel (*Pelagodroma marina*). Feeds by walking along beaches and intertidal zone, and also by plunge-diving; opens gastropods by dropping them on rocks or on other hard surfaces.
Breeding. Sept-Jan. Most colonies small and open, but 400 pairs at Wilson's Point (S Victoria); nests a few metres apart; often solitary. Builds sturdy nest of grass and seaweed; situated on ground among rocks, grass, shells. Lays 3 eggs (1-3); incubation 23-26 days. Very few other data available.
Movements. Most populations relatively sedentary, but young disperse up to 200 km. Post-breeding movement from Tasmania, N to Victoria and New South Wales coasts, uncommonly as far as Queensland. Accidental in interior and N Australia.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Although not at serious risk at present, species is nowhere common. About 100 breeding colonies known, but total population probably under 10,000 pairs. Expanded in early 20th century, and bred N to S Queensland. Range now shrinking somewhat in E, where it has suffered from competition with recently established and rapidly increasing population of *L. dominicanus*. In Tasmania, populations have been culled to protect other seabirds.
Bibliography. Barker & Vestjens (1989), Blakers *et al.* (1984), Boehm (1961), Brouwer & Garnett (1990), Coulson & Coulson (1993), Flegg & Magde (1995), Fleming (1987), Garnett (1993), James (1995), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1996), McGill (1955), Pizzey & Doyle (1980), Schodde & Tidemann (1986), Serventy & Whittell (1976), Serventy *et al.* (1971), Simpson & Day (1994), Slater *et al.* (1989), Sutton (1935), van Tets & Fullagar (1984), Wheeler (1946), Woodbury & Knight (1951).

3. **Belcher's Gull**

Larus belcheri

French: Goéland siméon **German**: Schwanzbandmöwe **Spanish**: Gaviota Simeón
Other common names: Simeon's/Band-tailed Gull

Taxonomy. *Larus Belcheri* Vigors, 1829, no locality (presumably Peru).
Formerly treated as polytypic, with *L. atlanticus* as a subspecies. Monotypic.
Distribution. Humboldt Current area, between N Peru (Libertad) and N Chile (Tarapacá). Disperses N to N Ecuador and S to C Chile (around Valparaíso).

Descriptive notes. 48-52 cm; wingspan 120 cm. White, with blackish brown mantle and upperwings, and broad black subterminal tail band; nape washed grey; bill yellow, with blackish subterminal ring and red tip; legs yellow; eyes dark, with red orbital ring. Very similar to *L. atlanticus*, but with slightly shorter wings and bill, grey wash on nape, brown tinge to mantle, and differently shaped tail band; bill slighter, with less pronounced gonydeal angle, while at tip the black is less extensive and the red paler. Non-breeding adult has a brownish hood extending below eyes, with a broad white eye-surround. Juvenile, with dark brown head, scaled greyish brown mantle, and brownish underwing with dark primaries, resembles *L. hemprichii*; tail black, with whitish base.
Habitat. Rocky shores and inshore guano islands.
Food and Feeding. Fish, crabs and shellfish, carrion; seabird eggs and young important during breeding season. Feeds along beaches and around bird colonies; scavenges in intertidal zone; at sea does not usually follow ships.
Breeding. From Dec. Scattered colonies, mostly of under 100 pairs, but occasionally exceeding 1000. Nest-site in hollow among rocks or on sand on shore, close to high tide line, or on steep rocky slope; often no nest built. Usually 3 eggs (1-3); darker olive brown than those of *L. dominicanus*. No information available on incubation and fledging periods, or appearance of chick.
Movements. Not studied. Most birds apparently remain close to breeding colonies, but some disperse N and S within Humboldt Current region; accidental to Panama. Three records from Florida may involve spontaneous occurrence.
Status and Conservation. Not globally threatened. Endemic to Humboldt Current region, with few known breeding sites. Total population certainly under 100,000 pairs, with centre of abundance at San Gallán I (C Peru). Relatively common in Peru, where more abundant than *L. dominicanus* in S; generally scarce and much less common than latter species in Chile. From early 1900's to 1960's, thousands of adults, eggs and chicks periodically killed to protect guano-producing species; however, destruction

California Gull (*Larus californicus*); 14. Great Black-backed Gull (*Larus marinus*).

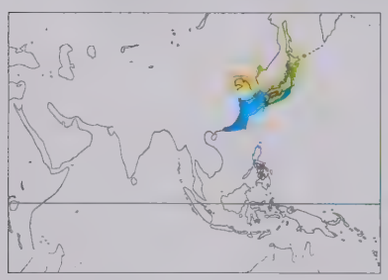
of 7000 eggs and young on San Gallán I did not effectively reduce population. Vulnerable to effects of El Niño (see Volume 1, page 341).
Bibliography. Blake (1977), Duffy (1983), Duffy *et al.* (1984), Hellmayr & Conover (1948), Johnson (1967), Koepcke, H.W. & Koepcke (1971), Koepcke, M. (1970), Meyer de Schauensee (1982), Moynihan (1962), Murphy (1936), Olson (1976), Olson (1985b), Parker *et al.* (1987), Ridgely & Gwynne (1989), Tovar (1965, 1968, 1974).

4. Olrog's Gull

Larus atlanticus

French: Goéland d'Olrog **German**: Olrogmöwe **Spanish**: Gaviota Cangrejera
Other common names: Simeon's/Band-tailed Gull

Taxonomy. *Larus belcheri atlanticus* Olrog, 1958, Mar del Plata, Argentina.
Originally described as a race of *L. belcheri*, but now almost universally considered a distinct species. Monotypic.
Distribution. SE Uruguay (R de la Plata) to Argentina (Puerto Deseado), but breeding known only in Argentina (Buenos Aires, Chubut).



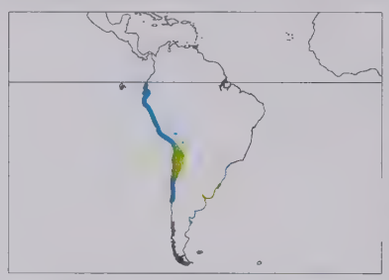
Descriptive notes. 50-56 cm; 900-960 g; wingspan 130-140 cm. White, with black mantle and wings; broad black tail band, except on outermost rectrices, with narrow white terminal band; bill yellow, with red and black tip; legs and feet yellow; iris blackish brown, with red orbital ring. Very like *L. belcheri*, but with slightly longer wings and bill, no grey wash on nape, no brown tinge to mantle, and differently shaped tail band; bill heavier, with sharper gonydeal angle, and at tip has the black more extensive and the red duskier.
Habitat. Coasts and estuaries, breeding on flat sandy islands. Non-breeders frequent sea coasts and riverbanks.
Food and Feeding. Specializes on crabs (*Chasmagnathus granulatus*, *Cyrtograpsus*, *Uca*), and on mussels; also takes fish and offal. Near breeding colony patrols along shores or swims among reeds, picking food items from surface; often hovers over water and then drops to surface. Much less predatory than *L. belcheri*. In Uruguay, feeds in large numbers on exposed mudflats or along rocky shorelines; does not associate with *L. maculipennis* or *L. dominicanus* near sewers or sea lion carcasses.
Breeding. From Sept, with large chicks in Nov. Colonies of 12-400 pairs, in subcolonies c. 50 m apart, at edge of large colonies of *L. dominicanus*; in beds of glasswort (*Salicornia*), among grass tussocks, or on bare ground, often far (100 m or more) from high tide line. Nest variable in form, ranging from flat scrape lined with vegetation to elevated platform of twigs and *Salicornia*; nests very densely crowded together, some even touching. 2-3 eggs. No further breeding details documented.
Movements. Post-breeding dispersal from colonies, S to Río Negro and Chubut, and N to Uruguay. Accidental in S Brazil and Tierra del Fuego.
Status and Conservation. VULNERABLE. Species appears to breed in very low numbers, and should perhaps be considered Endangered. Total known breeding population numbered under 1200 pairs in 1975-1977, and was estimated at 1239±127 pairs in 1992. Breeding distribution not fully documented, and only 6 colonies known, the largest with fewer than 400 pairs. Recent discovery of the Chubut breeding population, however, is very encouraging, and other colonies might still await discovery. Colonies vulnerable to disturbance and destruction through development of tourism, increased fishing, and petroleum exploitation; its eggs are regularly collected for food (e.g. at Bahía San Blas). Existing colonies require full protection and extensive study.
Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Collar & Andrew (1988), Collar, Crosby & Stattersfield (1994), Collar, Gonzaga *et al.* (1992), Contreras (1978), Daguerre (1933), Devillers (1977a), Escalante (1966), Gore & Gepp (1978), Harris & Yorio (1996), Hellmayr & Conover (1948), Klimaitis & Moschione (1987), Meyer de Schauensee (1982), Moynihan (1962), Murphy (1936), Olrog (1958, 1967, 1984), de la Peña (1992), Wege & Long (1995).

5. Black-tailed Gull

Larus crassirostris

French: Goéland à queue noire **German**: Japanmöwe **Spanish**: Gaviota Japonesa
Other common names: Temminck's Gull (Russia)

Taxonomy. *Larus crassirostris* Vieillot, 1818, Nagasaki, Japan.
Relationships unclear; some analyses place present species closest to *L. hemprichii*, others to *L. heermanni*. Monotypic.
Distribution. SE Russia (S Kuril Is, Sakhalin, Popov I, Moneron I, Peter the Great Bay), Japan, Korea and E China (Shandong). More widespread in winter, occurring S to N East China Sea.



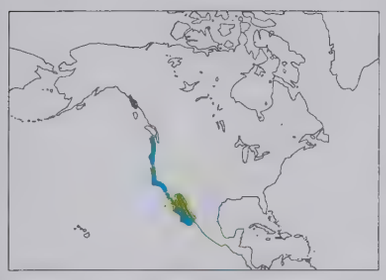
Descriptive notes. 44-47 cm; 436-640 g; wingspan 126-128 cm. Fairly distinctive gull, with white head and underparts, slaty mantle and upperwing, black primaries with white windows, and white tail with broad, even, black subterminal band; bill yellow, with red spot at tip and black subterminal ring, the latter with or without a red spot behind on lower mandible; legs greenish-yellowish. Juvenile dark brown, with whitish rump and belly, black primaries and tail tip, and black-tipped flesh-coloured bill; as adult after 4 years.
Habitat. Coasts, bays and estuaries; breeds on sandy or rocky seashores, sea cliffs, and rocky islets.
Food and Feeding. Diet varies locally and annually. Mainly small fish, crustaceans, insects and offal; also molluscs and polychaetes. In winter feeds heavily on commercial fish offal. In Hokkaido relied mainly on sardines (*Sardinops melanosticta*), but switched to sandeels (*Ammodytes personatus*) after former crashed in mid-1980's. Often follows fishing boats. Steals food from other seabirds, especially auks, gulls and terns. Visits rubbish dumps. Feeds by surface-seizing, occasionally immersing; also plucks prey from surface, and drops hard-shelled items onto hard surfaces to break them open.
Breeding. Colonies form mid-Apr, with laying May-Jun (Siberia). Many colonies hold over 10,000 pairs. Rough nest of dry grass; on sandy or rocky substrate. 2-3 eggs; incubation 24-25 days, rarely 27 days; chick greyish ochre to reddish ochre, spotted brown-black above and on throat; hatching weight 36-44·5 g; fledging 35-40 days. Predation highest near edge of colony. Fledgling survival 63-70%; main mortality due to neighbouring adults attacking wandering chicks.
Movements. Post-breeding dispersal to areas rich in food. 1st-year birds from Peter the Great Bay move to the maritime coast and the Tatar Straits. Birds from NW Honshu fly to the Pacific coast of Honshu, Hokkaido and S Sea of Okhotsk, while those from Yellow Sea spread N and S along its coast. Main wintering areas in Sea of Japan and N East China Sea, but particularly in Korea Strait; smaller numbers further S off Chinese coast, and on Pacific coast of Japan.
Status and Conservation. Not globally threatened. Total population estimated to be below 350,000 pairs, of which c. 100,000 in Russia (96% in Peter the Great Bay, including c. 80,000 on Furugelma I), and c. 150,000 in Japan. Colonies suffer some predation, mainly from corvids, and occasionally gulls; at some colonies many chicks taken by *L. schistisagus*, particularly late in season; feral cats may also take heavy toll. The commonest gull in Japan.
Bibliography. Armstrong (1983), Austin (1948), Austin & Kuroda (1953), Brazil (1991), Cheng Zhaoqin (1990), Étchécopar & Hüe (1978), Flint *et al.* (1984), Hasegawa (1984), Howell & Webb (1995a), Ilicev & Zubakin (1988), Knystautas (1993), Lekagul & Round (1991), Litvinenko (1980, 1986), Litvinenko & Shibaev (1991), Meyer de Schauensee (1984), Monroe (1955), Narita (1994), Perennou *et al.* (1994), Turton (1993), Wang (1991), Watanuki (1982, 1990, 1992, 1994), Williams, M.D. (1986), Yamashina (1961).

6. Grey Gull

Larus modestus

French: Goéland gris **German**: Graumöwe **Spanish**: Gaviota Garuma

Taxonomy. *Larus modestus* Tshudi, 1843, Lurin, south of Lima, Peru.
Most closely related to *L. heermanni*. Monotypic.
Distribution. Inland deserts (mainly Atacama) of N Chile and probably S Peru; feeding birds and non-breeders range along coast from Ecuador (Manta, virtually on equator) S to SC Chile (Valdivia).



Descriptive notes. c. 45 cm; 360-400 g. Unmistakable within range. Distinctive medium-sized, dull grey gull, with whitish head and black wingtips; darker above than below; pale trailing edge to wing; bill and legs black; iris brown. Differs from *L. heermanni* in somewhat smaller all black bill, and in overall plumage tone.
Habitat. Barren montane deserts, lacking vegetation and fresh water, 35-100 km inland. Feeds along sandy coastal beaches, eschewing rocky areas.
Food and Feeding. Mainly and sometimes exclusively mole crabs (*Eremita analoga*); also fish, nereid worms and offal. Mostly fish fed to young (only one feeding trip per day). Feeds in rather sandpiper-like fashion in wave-washed littoral zone, taking mole crabs from 1 hour before low tide to 2 hours after; surface-plunges for fish and nereid worms. Scavenges in harbours; follows fishing boats.
Breeding. Nov-Jan; eggs from mid-Dec. Does not breed in years with severe occurrence of El Niño. Colony of c. 60,000 nests in 5·5 km², with density of c. 1/m². Nest is a scrape in sand, usually near a rock. 1-3 eggs, usually 2 (mean 1·55, the lowest for any *Larus*); notably pale, sometimes white, with extremely low water-vapour conductance; incubation c. 29-31 days; one adult attends nest during day, while mate forages on coast; chick pale grey (occasionally buffy), with obscure black spots on sides of head, throat, back and flanks; hatching weight c. 31-38 g; brooded for several days, growth slower than in any other gull. Young fly to coast at c. 40 days.
Movements. During breeding season, daily movement of off-duty birds from coast to colony after dark, with mates returning shortly before dawn. No true migration, but non-breeding birds disperse N as far as Ecuador.
Status and Conservation. Not globally threatened. Abundant along Pacific coast, but generally less conspicuous inland. Total population exceeds 100,000 pairs. Egg-collecting can on occasion be serious, with up to 30,000 eggs recorded as being taken from a single colony; vast, uninhabited areas suitable for nesting remain, however, so some colonies should escape plunder. Breeding birds vulnerable to food shortage.
Bibliography. Blake (1977), Cikutovic *et al.* (1988), Devillers & Terschuren (1976a), Duffy (1983), Fitzpatrick *et al.* (1989), Fjeldså & Krabbe (1990), Goodall *et al.* (1945), Guerra & Cikutovic (1983a, 1983b), Guerra & Fitzpatrick (1987), Guerra, Aguilar & Fitzpatrick (1988), Guerra, Fitzpatrick & Aguilar (1988), Guerra, Fitzpatrick, Aguilar & Luna (1988), Guerra, Fitzpatrick, Aguilar & Venables (1988), Hellmayr & Conover (1948), Hilty & Brown (1986), Howell (1983a), Howell *et al.* (1974), Johnson (1967), Koepcke & Koepcke (1971), Moynihan (1962), Murphy (1936), Stiles & Skutch (1989), Tovar (1965, 1968), Wetmore (1965), Woods (1988).

7. Heermann's Gull

Larus heermanni

French: Goéland de Heermann **German**: Heermannmöwe **Spanish**: Gaviota Mexicana

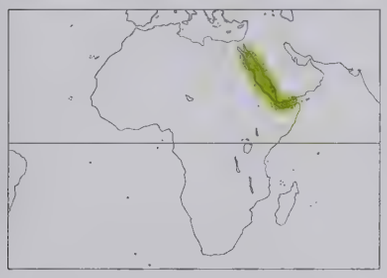
Taxonomy. *Larus Heermanni* Cassin, 1852, San Diego, California.
Monotypic.
Distribution. Breeds in Gulf of California (particularly Isla Rasa) S to Nayarit; also Baja California (from San Benito Is off Pacific coast) and N very sparsely in S California, occasionally and irregularly to San Francisco Bay.
Descriptive notes. 43-49 cm; 371-643 g; wingspan 117-124 cm. Distinctive medium-sized gull, with dark body and white head; grey-brown above, pale grey below, with pale grey rump and conspicuous white tips to tail and secondaries; bill bright red, often tipped with black; legs black; iris dark brown, with bright red orbital ring. Non-breeding adult has greyish or brownish streaks on head. Immature entirely dark brown, with pale base to bill; acquires adult plumage at 3 years.
Habitat. Wide range of coastal and estuarine areas; breeds on remote rocky coasts and islets with sparse vegetation.
Food and Feeding. Mainly fish in breeding season; also lizards, insects and other invertebrates. Associates with feeding sea lions to seize scraps of food; specializes on stealing fish from surfacing Brown Pelicans (*Pelecanus occidentalis*). Feeds mainly on beaches, estuaries and riverine marshes, by surface-plunging and surface-dipping.
Breeding. Egg-laying in late Apr; hatching from mid-May. Most colonies hold fewer than 100 pairs, one huge (Isla Rasa); species sometimes breeds among *L. occidentalis*, including solitary pair at Alcatraz I (San Francisco Bay), and 2 pairs at colony in San Luis Obispo County. On Isla Rasa, average nest

density 13·7/100 m² (range 8·2-20·5), densest in rock-free, flat-bottomed valleys; also on rocky slopes and in sparse vegetation (*Suaeda*) close to high tide line. 1-2 eggs, uncommonly 3 (mean 1·5-2·1); chick hatching weight 35-40 g; fledging 45 days. During food shortage, parents selectively feed one chick, and may attack third chicks. First breeding at 4 years, sometimes 3 years.

Movements. Post-breeding dispersal commonly to C California, and in smaller numbers N to British Columbia and S to Guatemala.

Status and Conservation. Not globally threatened. Currently considered near-threatened. Only eight colonies known, four of which are in Gulf of California. Total population 150,000 pairs or fewer; essentially stable since late 1960's. Species must be at risk, however, since 90% of total population nests on Isla Rasa, where estimates have varied alarmingly from 55,000 pairs in 1975 to 150,000 in 1990's. *L. livens*, if its population expands, could pose a serious threat through predation at this colony. Elsewhere in Gulf of California: 150 pairs on George I, 500 on Cholluda, and 4000 on Partida. Californian colonies small, and variable from year to year. Evaluating census data is difficult, because of different estimates of size of islands, variation in numbers of birds present at different times of year, and presence of non-breeding birds at some times.

Bibliography. Anderson (1983), Bartholomew & Dawson (1979), Blake (1977), Boswall (1978), Boswall & Barrett (1978), Cassidy (1990), Drury (1984), Everett & Anderson (1991), Howell, J. *et al.* (1983), Howell, S.N.G. & Webb (1995a), Jehl (1976), Land (1970), Rahn & Dawson (1979), Richards (1990), Root (1988), Schaldach (1963), Urrutia & Drummond (1990), Velarde (1992, 1993), Velarde & Anderson (1994), Wilbur (1987).



8. White-eyed Gull

Larus leucophthalmus

French: Goéland à iris blanc **German**: Weißaugenmöwe **Spanish**: Gaviota Ojiblanca

Taxonomy. *Larus leucophthalmus* Temminck, 1825, Red Sea coasts.
Morphometrically closest to *L. hemprichii*. Monotypic.

Distribution. Red Sea from Gulf of Suez and Gulf of Aqaba (Tiran) S into Gulf of Aden.

Descriptive notes. 39-43 cm; 275-415 g; wingspan 110-115 cm. Dark-backed gull, characterized by black head and upper breast with thin, slightly drooped bill; conspicuous white crescents above and below eye; dark grey underwing; legs bright yellow; iris dark brown, with red orbital ring. Separated from *L. hemprichii* by slender red bill with black tip, white eye-crescents, and paler upper breast sharply demarcated from hood. Juvenile dark grey-brown, very similar to juvenile *L. hemprichii*, but has large eye-crescents, paler head with streaked hindneck, heavily spotted throat, and slender drooping bill.

Habitat. Coastal, breeding especially on inshore islands, where occupies bare rock and sandflats. Less closely linked with fishing boats and harbours than *L. hemprichii*, thus often occurs further out to sea. Roosts on rocks, coral reefs, piers and fishing vessels.

Food and Feeding. Mainly fish; also some crabs, molluscs and annelids; even some fruits (*Nitraria retusa*). Feeds mainly by plunge-diving from surface. Less of a scavenger than *L. hemprichii*, but occasionally scavenges in harbours. Forages offshore in non-breeding season; usually in small groups, but sometimes gathers in flocks of hundreds or even thousands.

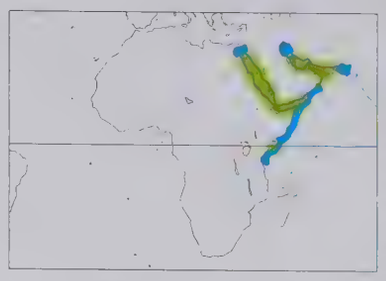
Breeding. Lays mainly in Jul; hatching complete by late Aug. Loosely colonial, in groups of about a dozen to hundreds; most colonies under 25 pairs. Nest on bare rock, sand, or exposed flats near sea; shallow scrape, lined with seaweed and debris. 2-3 eggs; chick greyish buff above with dark spots and streaks; incubation and fledging periods not documented.

Movements. Mostly sedentary; some dispersal and wandering, both N and S. Adults tend to remain along Red Sea coast. Small numbers seen throughout year at Elat, N Gulf of Aqaba. Accidental in E Africa.

Status and Conservation. VULNERABLE. Status poorly known. Total population estimated at 4000-6500 pairs in 1985. Most important sites in Egypt, at mouth of Gulf of Suez, where 1000-2000 pairs breed; elsewhere in Egypt, a few colonies with up to c. 50 pairs each; 350 at 10 sites in C Red Sea, mostly in colonies of less than 25 pairs. Colonies are subject to egging and collecting of chicks. Species is at permanent risk from effects of oil, both floating and beached; also from increasing human pressure of tourism and related activities, and from activities related to oil exploration.

Bibliography. Archer & Godman (1937-1961), Bednall & Williams (1989), Britton, P.L. (1980), Clapham (1964), Collar & Andrew (1988), Collar *et al.* (1994), Cowley (1981), Cramp & Simmons (1983), Dowsett & Forbes-Watson (1993), Étchécopar & Hüe (1964), Gallagher & Woodcock (1980), Gallagher *et al.* (1984), Goodman *et al.* (1989), Goodman & Storer (1987), Hollom *et al.* (1988), Hüe & Étchécopar (1970), Jennings *et al.* (1985), Mackworth-Praed & Grant (1957, 1962), Paz (1987), Perennou *et al.* (1994), Shirihai (1996), Symens (1991), Urban *et al.* (1986).

9. Sooty Gull



Larus hemprichii

French: Goéland de Hemprich **German**: Hemprichmöwe **Spanish**: Gaviota Cejiblanca
Other common names: Hemprich's/Aden Gull

Taxonomy. *Larus* (*Adelarus*) *hemprichii* Bruch, 1853, Red Sea.
Morphometrically linked with *L. modestus* and *L. leucophthalmus*. Monotypic.

Distribution. Red Sea and Gulf of Aden, and Persian Gulf and Gulf of Oman, E to S Pakistan, and S to N Kenya (Kiunga Is).

Descriptive notes. 43-48 cm; 400-510 g; wingspan 105-118 cm. Distinctive dark gull, with brown head and breast, white collar and greyish brown back and wings; short white eyebrow; heavy bill yellowish green, with red tip (extreme tip yellow) bordered at rear by black ring; legs dull yellowish olive; iris brown, orbital ring red. In all plumages (and especially immature) similar to *L. leucophthalmus*, but appears larger-bodied, longer-winged and stouter-billed. Non-breeding adult has head and foreneck pale brown, mottled with white, and no collar. Immature whitish-scaled pale brown above, with pale

rump, brownish tail with broad brown subterminal band, black iris, dark-tipped greenish grey bill, and greyish legs.

Habitat. Maritime, mainly occurring and breeding along coasts and at islands; hardly ever seen inland. Commonly associates with fishermen, following boats and frequenting harbours, or even sizeable ports, e.g. Karachi; sometimes feeds on mudflats. Frequently rests on piers, buoys and fishing boats.

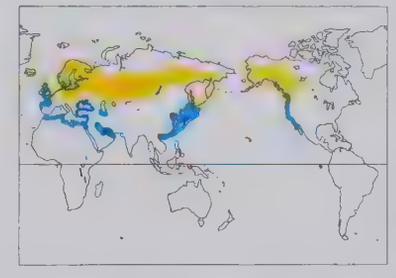
Food and Feeding. Mainly dead fish and offal; also tern eggs and chicks, and turtle hatchlings. Opportunistic; scavenges along shoreline, usually alone, but highly gregarious at times. Kleptoparasitic on conspecifics and other species; serious predator of other seabirds, including near-threatened Socotra Cormorant (*Phalacrocorax nigrogularis*); takes advantage of human intrusions to steal eggs; takes prawns or dead fish from nets (Pakistan). Rarely seen plunge-diving for fish. Feeds mainly inshore and in intertidal zone, occasionally up to 140 km offshore; follows ships.

Breeding. Summer breeder, laying in Jun at Hurghada (NW Red Sea), Jun-Sept in Pakistan, Jul-Oct in Kenya. Colonial, occasionally solitary; in Kiunga Is (Kenya), 1-3 pairs on each island among hundreds of terns. Nest a slight depression with scant vegetation lining, on bare coral (Kiunga Is), often under bush or overhanging coral, or sheltered by tuft of vegetation. 1-3 eggs; incubation c. 25 days; fledging period not documented, but some birds fledge in Nov.

Movements. Many remain in Red Sea throughout year. Post-breeding dispersal mainly S, sometimes as far as N Mozambique. Common winter visitor to Kenya, less common in Zanzibar. Mainly summer visitor to Pakistan; common in Karachi Port May-Jun, before dispersing to breed.

Status and Conservation. Not globally threatened. Size of total population essentially undocumented, but probably numbers 50,000-100,000 pairs. Two colonies off Arabia hold 5000 pairs each. Species uncommon in Persian Gulf; numbers breeding down coast of E Africa now much reduced, with perhaps only 50-100 pairs remaining. Numbers of non-breeding birds in Kenya increased between 1950's and 1970's. Main predation pressure comes from humans; most important colony in Pakistan (Astola I) is regularly robbed of eggs. Many colonies are vulnerable to oil spills.

Bibliography. Ali & Ripley (1982), Archer & Godman (1937-1961), Baha el Din & Saleh (1983), Bailey (1966), Britton, P.L. (1980), Cramp & Simmons (1983), Dowsett & Forbes-Watson (1993), Étchécopar & Hüe (1964), Fogden (1964), Gallagher & Woodcock (1980), Gallagher *et al.* (1984), Goodman & Storer (1987), Goodman *et al.* (1989), Hollom *et al.* (1988), Hüe & Étchécopar (1970), Jennings (1981a), Jennings *et al.* (1985), Mackworth-Praed & Grant (1957), Pakenham (1979), Paz (1987), Perennou *et al.* (1994), Rands *et al.* (1987), Richardson, C. (1990), Roberts, T.J. (1991), Shirihai (1996), Symens (1991), Urban *et al.* (1986).



10. Mew Gull

Larus canus

French: Goéland cendré **German**: Sturmmöwe **Spanish**: Gaviota Cana
Other common names: Common Gull (Eurasia); Short-billed Gull (*brachyrhynchus*)

Taxonomy. *Larus canus* Linnaeus, 1758, Sweden.
Sometimes considered to form a superspecies with *L. delawarensis*, but morphometric analysis links it instead with *L. melanocephalus*. *L. glaucus* is a synonym. Race *kamtschatschensis* sometimes treated as a separate species, but interbreeds with *heinei* in Siberia. Four subspecies recognized.

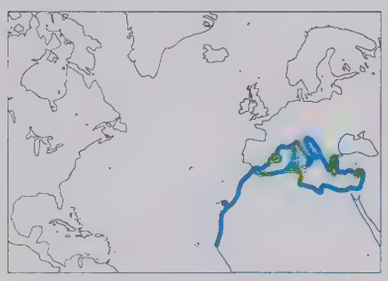
Subspecies and Distribution.
L. c. canus Linnaeus, 1758 - Iceland and British Is E to White Sea; winters from Europe to N Africa and Persian Gulf.
L. c. heinei Homeyer, 1853 - Russia, from Kanin Peninsula and Moscow area E to NC Siberia (R Lena); winters in SE Europe and at Black and Caspian Seas.
L. c. kamtschatschensis (Bonaparte, 1857) - NE Siberia; winters SE Asia.
L. c. brachyrhynchus Richardson, 1831 - N Alaska and N Mackenzie S to S British Columbia and N Saskatchewan; winters S to California.

Descriptive notes. 40-46 cm; 290-552 g, but *kamtschatschensis* 394-586 g; wingspan of *canus* 110-125 cm, of *brachyrhynchus* 96-102 cm. Typical white-headed gull, with white body and tail, and pale grey mantle and upperwing; outer 2 primaries black with large white subterminal patch, remainder grey with broad black areas and white tips; bill and legs greenish yellow; iris brownish. Much smaller than *L. argentatus*, and slightly smaller than *L. delawarensis*, with more slender, unmarked bill. Non-breeding adult has dusky streaks on head and neck, and bare parts duller; bill sometimes marked with black. Juvenile brown, mottled with buff; bill dark, with pinkish base. 1st-winter has rump, tail base, outer rectrices and underwing-coverts pale (*canus*) to dark (*brachyrhynchus*), and iris yellow (*kamtschatschensis*) to brown (*canus*). Achieves adult plumage at c. 27 months. Races differ in size and colour tone of upperparts, *kamtschatschensis* largest, adult *heinei* darkest.

Habitat. Coasts, tidal estuaries, agricultural land, reservoirs; breeds on coastal cliffs and islands, in beaches, bogs, marshes and meadows, not necessarily close to wetlands.

Food and Feeding. Earthworms, insects, aquatic and terrestrial invertebrates, small fish; grain (in spring); occasionally kills birds and small mammals. In Baltic, 73% fish. In British Columbia, takes euphausiids (*Thysanoessa raschii*) in winter. Follows plough, feeds on new-mown fields; foot-paddles on water and on soft ground. Exploits fish-processing areas; visits rubbish dumps less than some sympatric congeners, e.g. *L. ridibundus*. Occasionally kleptoparasitic; also occasionally uses aerial foraging, rarely hover-gleaning; swim-dipping and surface-dipping have been recorded. Drops molluscs from air onto hard surfaces.

Breeding. Lays usually in May. Typically breeds in small colonies; in Sweden mostly 2-10 pairs; in Britain largest 320 pairs; often solitary. Site tenacity lower in colonies, although colonies tend to be stable. In Sweden, colonial breeders experience lower nest predation than solitary nesters. Nesting substrates include grass, rock, sand, earth, floating vegetation, bogs, trees, dykes, roofs. Nest is a shallow cup of vegetation (larger at wet sites), often with some vegetative cover. Usually 3 eggs (1-3); incubation mostly 24-26 days (22-28); chick buff with heavy dark spots above, pale below; hatching weight c. 37 g; fledging 30-35 days, independent soon thereafter. Some adults give distraction display when flushed; pairs with vigorous anti-predator defence raise more young. First breeding usually at 3



years, occasionally 2, but normally no recruitment results from pairs younger than 5 years old. Recorded longevity of 24 years.
Movements. Fairly migratory. E Siberian birds winter from S Ussuriland coast and S Japan to SE Asia. C Russian breeders winter in Baltic, Black and Caspian Seas and in Middle East, some moving to S Asia. Those breeding in Finland winter from Denmark to Britain, while other European birds winter from Baltic to Brittany, with few reaching Mediterranean. Birds wintering in Scotland undergo synchronous emigration to Scandinavia in Apr. Alaskan birds winter along Pacific coast to Baja California.
Status and Conservation. Not globally threatened. Total population may exceed 1,000,000 pairs. Increasing and spreading in Europe, where in 20th century has colonized many new areas, including Iceland; breeds in Poland and Austria mainly since 1950's. Probably 72,000 pairs in Britain and Ireland, 60,000 in Denmark, 400,000 in Fenno-Scandia, and 50,000 in E Europe. Rapidly expanding populations have been controlled in some areas, e.g. E Germany. In Alaska, coastal survey counted 1700 pairs at 44 colonies, but at least 3 times that number breed inland along rivers, and total population probably over 10,000 pairs. Species suffers some predation at colonies, mainly from crows (*Corvus*), large owls (*Bubo*), large gulls, foxes and mustelids.

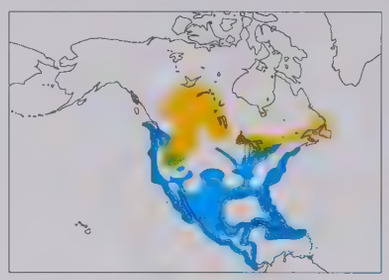
11. Audouin's Gull

Larus audouinii

French: Goéland d'Audouin **German**: Korallenmöwe **Spanish**: Gaviota de Audouin

Taxonomy. *Larus audouinii* Payraudeau, 1826, Sardinia and Corsica.
Probably closest to *L. canus*. Monotypic.
Distribution. Mediterranean coasts, with main breeding areas at Ebro Delta (NE Spain) and Chafarinas Is (off NE Morocco), scattered colonies E to Tunisia, Aegean Sea, S Turkey and Cyprus. Winters S to Senegambia.



Descriptive notes. 48-52 cm; 580-770 g; wingspan 125-138 cm. White-headed, white-bodied marine gull, with grey mantle and upperwings; characteristic profile, with elongated sloping forehead and a deep hooked bill; bill red, with black subterminal ring and narrow yellow tip (a few show a double black mark); legs dark greyish olive to blackish; iris dark, with crimson orbital ring. Paler than *L. cachinnans*, with more black on outer wings and reduced white windows; different bare part colours. Immature pale-backed, with dark outer wing. Juvenile has unform grey-brown face, with mottled back; black tail with broad white rump; bill dull yellow-green, with black tip.
Habitat. Coasts, bays and beaches, river mouths, fresh water beside coast; breeds mainly on offshore low, rocky islands among large stones and small bushes, on sandy beaches, or in low xerophytic scrub. Sometimes feeds over rice fields.
Food and Feeding. Relies mainly on fish, in particular clupeiforms, especially sardines; also insects and aquatic invertebrates, small birds, voles, plant matter (olives, peanuts and grain reported as locally important early in season); small passerines (particularly flycatchers), occasionally lizards and mice. Forages mainly at sea, sometimes quartering back and forth just offshore; joins other seabirds exploiting surface shoals of fish. Skims close to water and seizes fish from just below surface, without pausing. Readily exploits trawler discards (see page 598); during a moratorium on trawling, species shifted to feeding in marshes and rice fields, and also occasionally in rubbish dumps.
Breeding. Returns to colonies late Feb to mid-Apr; lays from late Apr; peak hatching late May. Colony size up to over 10,000 pairs (Ebro Delta, NE Spain); colonies usually monospecific, although sometimes breeds close to *L. cachinnans*; some colonies quite dense, up to 1 nest/m². Nest among rocks and vegetation, a scrape lined with debris. Usually 3 eggs (1-4, mean 1·9-2·8); incubation 26-33 days; chick pale grey-buff above, mottled dark brown, with marks forming stripes; hatching weight 46 g; fledging c. 35-40 days, with independence delayed to 3-4 months. Productivity sometimes very low.
Movements. Partially migratory, and dispersive. Disperses around coasts of Mediterranean; virtually all young birds and some adults pass Gibraltar to winter on coast of NW Africa, occurring S to Senegambia.
Status and Conservation. Not globally threatened. Conservation Dependent. Formerly considered Endangered, but now increasing slowly under protection. Colonies recently discovered in Aegean Sea and in Spain and Italy may have been newly established or overlooked. Inadequately known in 1981, this species is currently the most thoroughly censused of all gulls. As recently as 1966, total population was estimated at 800-1000 pairs, but in 1993 total estimated at 15,600 pairs in 30 colonies. It remains one of the most threatened seabirds, and a species of special concern; c. 72% of population breeds in two colonies: Ebro Delta, NE Spain, where no pairs at all in 1980, but 10,300 pairs in 1995; and in Chafarinas Is (off NE Morocco) with c. 2000 pairs in 1986, and 3500 in 1993; also c. 350 pairs in Italy, 210 pairs in Greece, and c. 500 pairs in Turkey. Species still threatened in E of range. Egging has a significant impact in some areas. Another threat at some colonies is from increasing *L. cachinnans* population, which pre-empts nest-sites and kills chicks, and rarely even adults; more chicks, however, are killed by conspecific adults. Predation by Peregrine Falcons (*Falco peregrinus*) is significant at some colonies, but probably has only minor effect on overall population. Extensive research and conservation work carried out in Spain in recent years (see page 598).

12. Ring-billed Gull

Larus delawarensis

French: Goéland à bec cerclé **German**: Ringschnabelmöwe **Spanish**: Gaviota de Delaware

Taxonomy. *Larus Delawarensis* Ord, 1815, Philadelphia.
Morphometric analysis links it most closely with *L. californicus*. W population significantly larger and possibly subspecifically distinct. Monotypic.
Distribution. N California, E Washington and interior British Columbia across prairie provinces and N mountain and plains states; Great Lakes to Maritime Provinces. Winters in S portion of breeding range S to Gulf Coast, Central America and Greater Antilles, increasingly ranging to Lesser Antilles.

Descriptive notes. 46-54 cm; 400-590 g; wingspan 121-127 cm. White head, body and tail, grey mantle and wings; slender yellow bill, with black subterminal ring in adults; iris bright yellow, with red orbital ring; legs yellow-green. Male averages 7% larger, with longer, deeper bill. Paler and slightly bigger than *L. canus*, with less white at wingtip. Non-breeding adult has heavily streaked head. Juvenile has pinkish legs, and black-tipped pinkish bill; attains adult plumage in 3rd winter.
Habitat. Coasts, rivers and estuaries, reservoirs, rubbish dumps; breeds on low-lying islands in freshwater lakes, on wet meadows, rarely on rivers.
Food and Feeding. Fish, insects, earthworms, other invertebrates, refuse and offal; also swarming ants, fiddler crabs, dates, fish eggs, grain, rodents and birds. On tidal flats in Maine species preferentially selected ragworms (*Nereis virens*). Highly opportunistic. Garbage used mainly in winter, in spring, and after young fledge. Also feeds behind plough, and on wet lawns; some nocturnal feeding on night-surfacing fish. Most food picked up from ground. Captures fish by plunge-diving, rarely by skimming along surface. Kleptoparasitism reported.
Breeding. Lays late Apr to May; in N of range often delayed by snow cover. Colonies often very large. Large, bulky nest, often beside rock, driftwood or vegetation; often within 1 m of neighbour; nest-sites reused year after year, often by same pair. 3 eggs (mean 2·7-2·9); incubation 25-28 days; chick semi-precocial, hatches with eyes closed, remains in nest 24-48 hours, leaves nest-site by 4th day; small crèches may be formed in some colonies; fledging c. 37 days; departs from colony at c. 45 days.
Movements. Wanders N to Alaska and Yukon. Winters from S part of breeding range S to Greater Antilles; becoming commoner in Central America, both in the interior and along coasts; also occurs increasingly in Lesser Antilles; first recorded in Florida in 1930, now common in winter. E population migrates to Atlantic coast and S to Gulf Coast, few reaching West Indies and Central America. Birds of plains and mountain states move to Pacific coast. Large numbers remain on Great Lakes until freeze-up. Most Great Lakes birds return to the lake where they hatched, but not necessarily to same colony. Since mid-1970's has become regular vagrant to W Palearctic (see page 595), especially in British Is, where records span all months of the year; massive influx of over 400 individuals in first half of 1980's has led to species becoming a virtual resident in some coastal areas.
Status and Conservation. Not globally threatened. Population now estimated at c. 1,500,000-2,000,000 pairs. Declined dramatically during late 19th century, and fears were expressed for its future. In recent decades, however, an enormous increase has occurred. Now an abundant species, particularly on the Great Lakes, where its population has grown exponentially throughout 20th century to nearly 500,000 pairs, and where it is now considered a serious pest to other breeding birds. On Little Galloo I, L Ontario, increase from: c. 20,000 pairs in 1950; to 45,000 in 1955; 63,000 in 1961; 85,000 in 1968; and stabilized at c. 74,000 pairs from 1981, suggesting saturation. On L Huron and L Michigan, 27,000 pairs in 1960 increased to 150,000 by 1974. Range expanded greatly in mid-20th century. First bred in New York in 1936, California in 1940, and British Columbia in 1974.

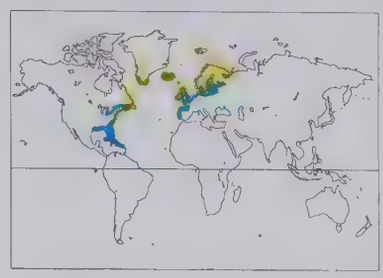
13. California Gull

Larus californicus

French: Goéland de Californie **German**: Kalifornienmöwe **Spanish**: Gaviota Californiana

Taxonomy. *Larus Californicus* Lawrence, 1854, Stockton, California.
Fossil from late Pleistocene of Oregon. The races, formerly disjunct, have recently come together in N plains, where a zone of secondary contact is forming; genetic studies have shown little divergence between them. Two subspecies currently recognized.

Subspecies and Distribution.
L. c. albertaensis Jehl, 1987- S Mackenzie (Great Slake L), Alberta and W Manitoba to South Dakota.
L. c. californicus Lawrence, 1854 - E Washington and Great Basin to C Montana and Wyoming.
Winters mainly from SW Canada to SW Mexico.



Descriptive notes. 51-58 cm; *californicus* 432-885 g, *albertaensis* 568-1045 g; wingspan 122-140 cm. Typical white-headed gull; bill yellow, with red gonydeal spot edged in black; legs yellowish; iris dark brown, with red orbital ring. Male averages 6% larger than female, with head and bill c. 8% larger. Non-breeding adult has heavy brown streaking on head and neck. Juvenile dusky brown with creamy buff edges, all black primaries, all brown tail, and bill with sharply defined black tip. Race *albertaensis* larger, with paler mantle.
Habitat. Coasts, estuaries, bays, mudflats, marshes, freshwater wetlands, lawns, agricultural fields; breeds in open habitats in arid interior, usually on low rocky islands in both freshwater and hypersaline lakes.
Food and Feeding. Insects and grubs (especially Orthoptera), bird eggs and young, earthworms, crabs, rodents, carrion, rubbish, fruit and grain; locusts are commonest animal matter, although bird eggs the highest volume. Renowned for destruction of crickets, grasshoppers. In British Columbia, fed mainly on grain at one colony, rubbish at a second, and insects at a third. Some populations specialize on bird eggs; capable of killing chicks of Canada Goose (*Branta canadensis*); may almost eliminate duck production on some lakes. Eats carcasses of adult birds killed by botulism, as well as road-killed animals. Takes rodents when these are abundant, particularly when flooded out of their burrows. Can be a serious pest at cherry and strawberry farms. Feeds mainly by picking; also surface-plunges, e.g. for crabs.
Breeding. Returns to colonies in early Mar; lays late Apr to May; hatching mostly from early Jun (mid-May). Mated pairs tend to be of same age, probably because of long-term monogamy. Upper Critical Density (UCD) of colonies c. 50 pairs/100 m², but no depression of productivity even at 77 pairs/100 m²; centrally located sites with protective shrubs support high density nesting, and are more productive; in years of high density, territorial aggression increases adult mortality through injury. Lays 3 eggs in most of range (over 80% of clutches in British Columbia), but normally 2 in Great Basin (e.g. Mono L); at Mono L, 2-chick broods more successful than those of 1 or 3; incubation 26-28 days; chick whitish, with buff band across with breast, mottled dark brown blotches above, blacker and more sharply defined on head; fledging c. 40 days. Chicks of older parents grew more rapidly and were more likely to fledge. Productivity from 0·12/nest for 1-egg clutches to 0·35/nest for 2-egg clutches.
Movements. Wanders to SE Alaska. Winters mostly along Pacific coast to S Baja California and Colima, and locally elsewhere in Mexico. Saskatchewan breeders migrate W to coastal British Columbia, then disperse S as far as Sinaloa.
Status and Conservation. Not globally threatened. Total population approaching 200,000 pairs at over 100 colony sites. Numbers were seriously reduced by commercial egging in late 19th century, but from early 20th century species was protected, and even esteemed, for its role in destroying crickets. In mid-1930's, however, reported as an agricultural pest on cherries, and more recently recognized as a serious predator on ducks. USA population grew at 2% per year, from c. 50,000 pairs in 1930 to nearly 140,000 in 1980, while number of colonies increased from 15 to 80. There were at least 17,000 pairs at known colonies in Canada. Largest colonies are at Great Salt L and Mono L. Population increase has been accompanied by range expansion.
Bibliography. Ainley & Hunt (1991), Armstrong (1983), Behle & Goates (1957), Bent (1921), Clapp *et al.* (1982), Conover (1983b, 1984b), Conover & Conover (1981), Conover & Hunt (1984b), Conover & Miller (1980), Conover, Miller & Hunt (1979), Conover, Thompson *et al.* (1979), Drury (1984), Greenhalgh (1952), Hayward *et al.* (1982), Howell & Webb (1995a), Jehl (1987b, 1989, 1994a), Jehl & Chase (1987), Jehl & Mahoney (1987), Jehl, Babb & Power (1984, 1988), Jehl, Francine & Bond (1990), Johnston (1956a, 1956b), Karl *et al.* (1987), Mahoney & Jehl (1985a), Nur (1984), Pugesek (1981, 1983, 1984, 1987, 1990, 1993), Pugesek & Diem (1983, 1986, 1990), Richards (1990), Root (1988), Schnell *et al.* (1985), Smith & Diem (1972), Southern (1980), Vermeer (1969), Wahl (1977), Winkler (1985), Winkler & Shuford (1988), Young (1952), Zink & Winkler (1983).

14. **Great Black-backed Gull**

Larus marinus

French: Goéland marin **German**: Mantelmöwe **Spanish**: Gavión Atlántico

Taxonomy. *Larus marinus* Linnaeus, 1758, Gotland, Sweden.
Monotypic.
Distribution. Great Lakes, E Canada and USA to North Carolina; S Greenland; Iceland, Faeroes, British Is, NW France and Scandinavia E to at least White Sea, including Bear I and Spitsbergen. Winters S to West Indies and Iberia, occasionally reaching Morocco.

Descriptive notes. 68-79 cm; 1435-2272 g; wingspan 152-167 cm. Largest gull; large-winged, with massive head and bill, particularly in male; white head, underbody and tail, with slaty black back and upperwings; bill yellow, with red gonydeal spot; legs pink; iris yellow, with red orbital ring. Juvenile heavily mottled white and pale brown, with all dark bill. Immature similar, but with distinctive whitish head and breast; black subterminal tail band; bill pale, with dark tip.
Habitat. Rocky or sandy coasts, estuaries and open sea; locally larger inland waters, fields and moorland; breeds on vegetated islands, dunes, flat-topped stacks, sometimes salt-marsh islands among bushes, and locally on buildings.
Food and Feeding. Omnivorous and opportunistic. Fish, adult and young birds, bird eggs, mammals, marine invertebrates, insects, carrion, rubbish, offal and berries. Fish include e.g. cod (*Gadus morhua*), herring (*Clupea harengus*), capelin (*Mallotus villosus*). Aggressive predator, particularly on eggs and chicks of *L. argentatus*, *Rissa tridactyla*, ducks, seabirds, and other species. Can kill adult birds: has major impact on alcid populations in Scotland, but perhaps not in Newfoundland; seriously impairs Common Eider (*Somateria mollissima*) productivity; takes large numbers of Manx Shearwaters (*Puffinus puffinus*). Eats rodents, rabbits, lemmings, rats and mice; occasionally young lambs (Iceland); sometimes fruits. Cracks molluscs and goose eggs by dropping them on hard surfaces; kills young birds in same way. Scavenges on shore, also at rubbish dumps. Some reports of kleptoparasitism.
Breeding. Lays from early Apr in S to mid-May in N. Usually small colonies, near or intermingled with *L. argentatus*, and often solitary pairs among other species; few large colonies (e.g. 700 pairs at Placentia Bay, Newfoundland); chick mortality increases with number of neighbouring territories and frequency of agonistic encounters. Prefers ridges, pinnacles and rock outcrops, but some nest on roofs; normally uses open sandy, grassy or rocky substrate. Bulky nest of dry grass, moss and seaweed, often next to rock or vegetation; nearest-neighbour distance in colonies 5-20 m; shows nest-site tenacity. Adults more aggressive to non-neighbouring intruders than to neighbours. Usually 3 eggs (1-3); incubation c. 26-28 days; chick pale grey with large black spots; hatching weight 80-90 g; fledging c. 7-8 weeks. Productivity often high. First breeding at 4-5 years.
Movements. Variable. High Arctic birds migrate S, while southern breeders disperse shorter distances. Most Icelandic birds disperse around the island, but some juveniles reach Britain. Complex pattern, since Norwegian birds move mainly W and SW to North Sea and Britain, while Swedish and Finnish breeders move mainly E and S into Baltic. North American recoveries were all within 800 km of breeding colony, but numbers reaching Gulf Coast are increasing, and a few reach West Indies.
Status and Conservation. Not globally threatened. Total population at least 200,000 pairs, with c. 30% in Norway. Population of W Palearctic under 200,000 pairs, including 23,000 in British Is in 1987. Greenland c. 10,000 pairs; E North America tallied 17,415 pairs in 1983. Has increased and extended range S between 1930's and 1975, as well as spreading N to Spitsbergen, but breeding populations appear to have stabilized since then, perhaps related to closing of landfills. Increased greatly in Iceland in 20th century, and now the commonest large gull there. In Nearctic, range has extended S considerably since mid-20th century; first bred in Maine in 1928, Massachusetts in 1931, New York in 1940, Great Lakes in 1954, and New Jersey in 1966; New England population increased from 30 pairs in 1930 to 12,400 in 1972. Species is considered a threat to other bird species, particularly eiders, and control measures were advocated as early as 1945.

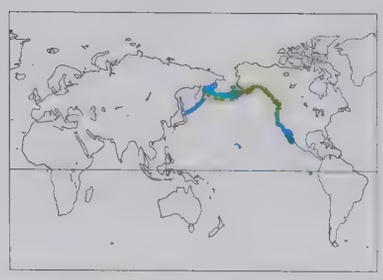
15. Kelp Gull

Larus dominicanus

French: Goéland dominicain **German**: Dominikanermöwe **Spanish**: Gaviota Cocinera
Other common names: Dominican Gull (New Zealand), Southern Black-backed Gull (Africa, Australia)

Taxonomy. *Larus dominicanus* Lichtenstein, 1823, coasts of Brazil.
South Shetlands population formerly separated as *austrinus*, but matched by birds elsewhere in S of range. Some authors give subspecific status to South African population, race *vetula*, based mainly on its mottled brown iris. Monotypic.
Distribution. S Africa, from Namibia (Cape Cross) to Cape Province (Algoa Bay), and S Madagascar; S Australia and New Zealand; N Peru and S Brazil (São Paulo) S to Tierra del Fuego, and Falkland Is; subantarctic islands and Antarctica.



Descriptive notes. 54-65 cm; 900-1335 g; wingspan 128-142. Typical large, white-headed, black-mantled gull, with white tail; black upperwings with white trailing edge and white windows at tips; bill yellow, with red gonydeal spot; legs greenish yellow, greyer in Africa; iris yellow, with red to orange-red orbital ring. Similar to *L. pacificus*, but lacks black tail band and has thinner bill. In Africa, distinguished from *L. fuscus* by greyish rather than yellow legs, and heavier bill and body. Non-breeding adult has some brown mottling on head and neck. Juvenile dark brown, speckled with buff and whitish on head, neck, back and underparts; flight- and tail feathers dark brown with buff edges, secondaries and scapulars tipped with white. Immature has much white on rump and tail; 3rd-year similar to non-breeding adult; full adult plumage achieved in 4th year.
Habitat. Mainly coastal regions, exclusively so in S Africa, but elsewhere often visits large inland lakes (e.g. in Andes of Argentina), and feeds or roosts at lakes (including mountain tarns in New Zealand), reservoirs, estuaries and rivers, and on lawns and farmland; breeds on oceanic and offshore islands, headlands, sea cliffs, beaches, pastures, lava fields, rocky islands in rivers and urban areas.
Food and Feeding. Very varied. Molluscs, fish, echinoderms, worms, arthropods, reptiles, amphibians, small mammals, birds and occasionally swarming termites (*Microhodotermes viator*); scavenges rubbish, fish offal, sewage and carrion; steals food from terns. Occasionally takes sickly lambs and young poultry; may attack and kill adult birds as big as geese. In Antarctica main food is Antarctic limpet (*Nacella concinna*). At Valdés Peninsula, SC Argentina, associates with right whales (*Eubalaena glacialis*), capturing stirred-up invertebrates; also lands on whales and eats living flesh. Frequents slaughterhouses and also fish and seafood factories; sometimes at sewage outfalls; follows boats at sea. Feeds by plunge-diving, dabbling in water and picking from ground; also opens shellfish by dropping them onto hard surfaces.
Breeding. Oct in S Africa, Sept-Dec in Australia, mid-Oct to Jan in New Zealand, mid-Nov on subantarctic islands, Dec in Falklands; mainly Oct-Dec in South America, but on guano islands at any time (cycle adjusted to seabird breeding). Usually in colonies of dozens (particularly at edges of range) to 100's of pairs, occasionally solitary; nest density 20-106 nests/ha. On sandy or rocky substrates, often well vegetated; bulky nest of dried plants or seaweed, often at base of bush, tree, rock or other vertical structure. 3 eggs; incubation 24-30 days; fledging c. 7 weeks.
Movements. In S Africa, non-breeding visitor as far as Mozambique. In Australia, non-breeding birds disperse N to Queensland, and along S coast; accidental on N coast and in interior. Some N movement of New Zealand birds, but many remain near breeding grounds. Falklands birds are resident, but disperse widely around the islands, while some of those from S South America migrate N to winter with their subtropical counterparts. Birds remain in Antarctica throughout year, frequenting open water away from pack ice.
Status and Conservation. Not globally threatened. Common and conspicuous over much of range. Over 1,000,000 pairs in New Zealand, perhaps 50,000 in South America and Falklands, 15,000 in S Africa, and 10,000-20,000 in Antarctica and subantarctic; only a few hundred pairs (but increasing) in Australia, where first seen in 1943, first bred in 1958, and now breeds from S Western Australia E around coast to Tasmania and New South Wales. Has increased throughout range with expansion of agriculture and fisheries.

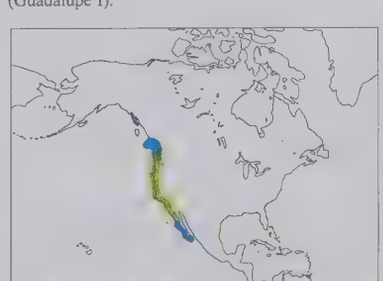
16. Glaucous-winged Gull

Larus glaucescens

French: Goéland à ailes grises **German**: Beringmöwe **Spanish**: Gaviota de Bering

Taxonomy. *Larus glaucescens* J. F. Naumann, 1840, North America.
Fossil from late Pleistocene, prehistoric specimens from Alaska and California. Closely linked with *L. hyperboreus* and *L. argentatus*, and hybridizes with both. Hybridizes freely with *L. occidentalis* from S British Columbia to Oregon, and by some authors treated as conspecific. Monotypic.
Distribution. Commander Is E through Aleutians, Pribilofs and S Bering Sea to S Alaska, then SE to N Oregon. Winters from Bering Sea to N Japan and Baja California.
Descriptive notes. 61-68 cm; 900-1250 g; wingspan 132-137 cm. Head, body and tail white; thick bill yellow, with red gonydeal spot; legs flesh-coloured; iris dark brown, with dull red orbital ring. Like *L. argentatus*, but bulkier, with paler grey mantle, and pale grey rather than black primaries. Non-breeding adult has head and neck streaked with brownish grey; in autumn the red gonydeal spot becomes obscured with black in c. 90% of adults. Immature pale greyish with pale mottling; tail ashy grey; bill blackish. Hybrids with *L. hyperboreus* and *L. argentatus* (S Alaska) often have dark iris (*L. glaucescens* trait); hybrids with *L. argentatus* may have dark grey (but not black) primaries (*L. argentatus* trait), but back-crosses can resemble either parental species, as well as *L. thayeri*. Hybrids with *L. occidentalis* (which in some areas outnumber both parental types) have intermediate mantle colour and primaries, and are similar to *L. argentatus*; difficult to identify outside their normal range.



Habitat. Coastal areas and shelf waters; breeds on barren, rocky or vegetated islands, bays and estuaries, grassy meadows, cliffs, inland lakes (Alaska), city parks, breakwaters and buildings (on roofs), showing preference for smaller, flatter, and less forested islands with more bare rock and low herbaceous cover.
Food and Feeding. Fish, various marine invertebrates (e.g. mussels, barnacles, crabs, starfish, sea urchins), carrion, offal, bird eggs and small mammals. In breeding season, predominant foods vary from invertebrates to fish, to birds; at Cape Thompson (Alaska), fed mainly on murre (*Uria*) eggs; on W coast of Vancouver ate gooseneck barnacles (*Pollicipes polymerus*), and fed sandeels (*Ammodytes hexapterus*), herring (*Clupea harengus*) and sauries (*Colalabis saira*) to chicks. Cannibalistic in colonies. Swims in rivers and plucks salmon roe; feeds on remains of bear-killed or dying fish during spawning runs; exploits raptors for their catches. Feeding habitats vary with local conditions and competitors; favours intertidal zones near some colonies, avoids them elsewhere. Variety of feeding methods including plunge-diving, diving from the surface, walking etc.; drops shellfish on rocks. Makes daily round trips of up to 140 km to feeding grounds (e.g. Vancouver).
Breeding. Arrives back at colonies in Feb-Mar; lays from early May in Washington, early Jun in Alaska. Older birds breed earlier in season; 95% retain mates between years. Usually colonial (up to 2000 pairs), often solitary, including nests on some artificial structures. Nests on various substrates, often in the open, but shifts to denser colonies when Bald Eagles (*Haliaeetus leucocephalus*) are present, the eagles taking adult gulls, as well as chicks. Mean territory size 5-20 m². Usually 2-3 eggs (1-6, mean 2·82); incubation 26-28 days; chick grey-brown, tinged yellowish below, with blackish blotches; fledging c. 45 days. Breeding success often rather low; c.45% of chick mortality inflicted by neighbouring adults, with mortality heaviest in 1st week. Average age of first breeding 5·4 years, with no difference between sexes.
Movements. Some birds remain on territory all winter, but most move S; some wander S of Bering Sea into open N Pacific. Alaskan birds move S ahead of ice margin. 1st-year birds migrate further (up to 2000 km), some reaching Baja California. Stragglers reach coast of China.
Status and Conservation. Not globally threatened. Total population probably c. 250,000-300,000 pairs. In Alaska 135,000 pairs at over 600 sites, and increasing; marginal in Commander Is, with few thousand pairs. Has expanded S and N, leading to increased hybridization with *L. occidentalis* in Washington and with *L. hyperboreus* in Alaska. Is now becoming a nuisance in cities, and a safety risk at airports. Foxes cause this gull to desert some breeding islands.

17. Western Gull

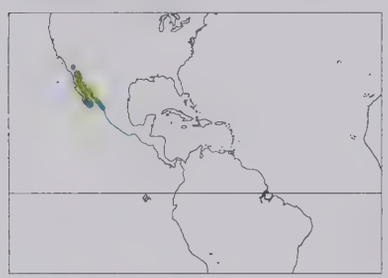
Larus occidentalis

French: Goéland d'Audubon **German**: Westmöwe **Spanish**: Gaviota Occidental

Taxonomy. *Larus occidentalis* Audubon, 1839, Cape Disappointment, Washington.
Interbreeds freely with *L. glaucescens* at N end of range. Two subspecies recognized.
Subspecies and Distribution.
L. o. occidentalis Audubon, 1839 - NW Washington (Destruction I) to C California (Farallon Is).
L. o. wymani Dickey & Van Rossem, 1925 - C California (Monterey Bay) to C Baja California (Guadalupe I).

Descriptive notes. 54-66 cm; 800-1190 g; wingspan 132-142 cm. Typical large, white-headed gull with dark mantle; bill bright yellow, with red gonydeal spot; legs and feet pink; iris amber-yellow, with orange-yellow to pinkish yellow orbital ring. Larger than *L. fuscus*, with more sloping head, and longer, heavier bill; iris darker than in *L. argentatus* and *L. fuscus*; gonydeal spot smaller and rounder than in other dark-mantled gulls. Non-breeding adult has moderately streaked head. Juvenile mottled dark brown, with pale-barred rump, blackish flight-feathers, and black bill. Immature has pale head and underparts, grey back, and flesh-coloured bill base. Races differ in mantle colour, slaty in *occidentalis*, blacker in *wymani*; non-breeding adult *wymani* has less head streaking.
Habitat. Essentially confined to the coast, generally straying only a few kilometres inland; breeds on rocky islets with some herbaceous cover and gravelly beaches, often near California sea-lions (*Zalophus californianus*).

On following pages: 18. Yellow-footed Gull (*Larus livens*); 19. Glaucous Gull (*Larus hyperboreus*); 20. Iceland Gull (*Larus glaucoides*); 21. Thayer's Gull (*Larus thayeri*); 22. Herring Gull (*Larus argentatus*); 23. Yellow-legged Gull (*Larus cachinnans*); 24. Armenian Gull (*Larus armenicus*); 25. Slaty-backed Gull (*Larus schistisagus*); 26. Lesser Black-backed Gull (*Larus fuscus*).



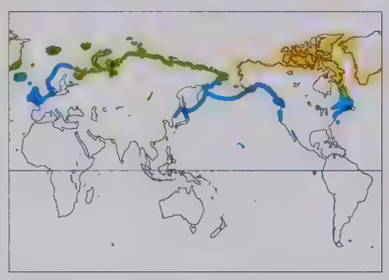
Food and Feeding. Very varied. Marine fish and invertebrates; eggs, chicks and adults of seabirds; carrion; occasionally moves up rivers to exploit spawning salmon. At Farallon Is, takes rockfish (*Sebastes jordani*). Predation on seabirds increases when other foods scarce. Associates with seals, and eat placentae; may attack and kill newborn pups. A few individuals, mainly males, establish feeding territories in alcid or cormorant colonies, feeding mainly by predation, piracy and scavenging; these specialists occupy same territory year after year. Much food obtained by scavenging. Drops shellfish onto rocks to break them.
Breeding. Lays late Apr to early May, later in N. Colonial, with inter-nest distances ranging from 1·75 m in centre to over 30 m at periphery; killing of neighbouring chicks more serious in dense areas. Sites on ridges of islands preferred. Nest on barren substrate, surrounded by stones, guano and feathers. Usually 3 eggs (1-5, mean usually 2·3-2·7); in some colonies 4- and 5-egg clutches common (from female-female pairs), but these have lower hatching success, and eggshells thinner; incubation 23-28 days; chicks under 10 days attended 97% of time, fed by both parents; in one study, males made equal number of feedings but provided lower-quality food; fledging c. 6 weeks, but parental care continues until at least 70 days. Hatching success 55-80%. Young chicks are vulnerable to heat stress, and heatwaves cause mass mortality, particularly in microhabitats with low wind velocity. Age at first breeding 4·8 years for males, 6·2 years for females; average number of breeding seasons 6·2 years for males, 5·2 for females.
Movements. Post-breeding movement to British Columbia and accidentally to peninsular Alaska, also S to the tip of Baja California and occasionally to Sonora coast of Mexico. Birds from S colonies disperse, those from N colonies migrate S. Migration distance correlated with latitude, and young birds move further than adults. Farallon Is birds are mainly sedentary, adults maintaining breeding territories most of year. Young birds disperse N to areas of high oceanic productivity in summer, and move S to San Francisco Bay in winter. Dispersal of young varies from year to year, depending on food availability, but adults tend to return to the same site each winter.
Status and Conservation. Not globally threatened. Common in most of its range, but total population only c. 32,000 pairs (certainly less than 50,000); the rarest gull in North America. Altogether 13,000 pairs (c. 40% of population) breed on Southeast Farallon I, which lies in a major shipping channel. Subject to effects of pesticides, oil pollution, and consequences of El Niño (see Volume 1, page 341); also to human disturbance, which lowers productivity. Hybridization with *L. glaucescens* is an adverse factor in the maintenance of the species. Is frequently subjected to control measures of wildlife managers, seeking to protect other species of waterfowl and seabirds which may actually be far more numerous.
Bibliography. Ainley & Hunt (1991), Annett & Pierotti (1989), Aurioles & Llinas (1987), Bayer (1983), Bent (1921), Carter & Spear (1986), Clapp *et al.* (1982), Coulter (1970, 1975, 1977), DeSante & Ainley (1980), Drury (1984), Everett & Anderson (1991), Ewald *et al.* (1980), Hand (1980, 1981b, 1986), Hand *et al.* (1981), Harper (1971), Hoffman *et al.* (1978), Howell & Webb (1995a), Hunt & Hunt (1973, 1975, 1976a, 1976b, 1977), Hunt *et al.* (1980), Maron (1982), McCaskie (1983), Pearse (1946), Pierotti (1981), Pierotti & Annett (1995), Pierotti & Bellrose (1986), Pyle *et al.* (1991), Robert & Ralph (1975), Richards (1990), Root (1988), Salzman (1982), Sayce & Hunt (1987), Schreiber (1970), Scott (1971), Southern (1980), Spear (1980, 1988, 1993), Spear & Nur (1994), Spear, Henderson & Ainley (1986), Spear, Penniman *et al.* (1987), Spear, Sydeman & Pyle (1995), Sydeman & Emslie (1992), Sydeman *et al.* (1991).

18. **Yellow-footed Gull**

Larus livens

French: Goéland de Cortez **German**: Gelbfußmöwe **Spanish**: Gaviota de Cortés

Taxonomy. *Larus occidentalis livens* Dwight, 1919, San José Island, Baja California.
Until recently treated as a race of *L. occidentalis*, but differs in vocal repertoire, particularly its lower-pitched long call. Some authorities consider it more closely related to, and perhaps derived from, *L. dominicanus*. Monotypic.
Distribution. NW Mexico, in Gulf of California; rare in S California, USA.



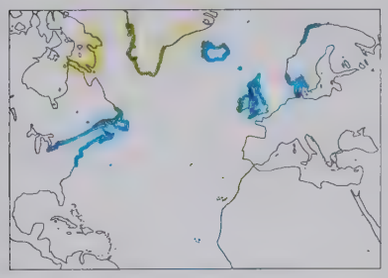
Descriptive notes. 60-67 cm; 1110-1400 g; wingspan 142-155 cm. Typical white headed, dark-mantled gull; iris yellow. Separated from *L. occidentalis* most clearly by yellow legs; also slightly larger size, and heavier bill. Juvenile differs from juvenile *L. occidentalis* in whiter underparts and rump, and bolder spotting on back; head dark, intermediate between *L. occidentalis* and *L. argentatus*.
Habitat. Sandy and rocky islands, usually with little or no vegetation.
Food and Feeding. Fish, invertebrates, carcasses of marine mammals, and offal; takes small seabirds (petrels), pelican eggs, crabs, fish and food scraps. Preys on eggs and young of *L. heermanni* and Elegant Tern (*Thalasseus elegans*), and is a serious threat at some colonies.
Breeding. Essentially undescribed. Egg-laying in early Apr. Most colonies under 100 pairs; occasionally solitary. To reduce heat stress, nests are distributed in linear form, parallel to high tide line, allowing unimpeded access to water. Mean nearest-neighbour distance in 9 colonies 594-1070 cm.
Movements. Some post-breeding dispersal N to Salton Sea, and rarely to Californian coast; disperses S to Sonora, and rarely to Guerrero.
Status and Conservation. Not globally threatened. Probably requires reclassification as Vulnerable, due to very low numbers and small range. Population possibly as low as 3600 pairs in 11 documented colonies, ranging from 200 to 600 pairs each. Shows some local increases which may jeopardize other seabirds. One of the least studied and least known of all gull species, and also clearly one of the least numerous; extensive research needed on biology, ecology, status, trends, and conservation requirements.
Bibliography. Anderson (1983), Devillers *et al.* (1971), Drury (1984), Dunning (1988), Dwight (1919), Everett & Anderson (1991), Hand (1981b), Howell & Webb (1995a), McCaskie (1983), Penniman *et al.* (1990), Richards (1990), Rodríguez-Estrella *et al.* (1995), Spear & Anderson (1989), Velarde (1992), Velarde & Anderson (1994), Wilbur (1987).

19. **Glaucous Gull**

Larus hyperboreus

French: Goéland bourgmestre **German**: Eismöwe **Spanish**: Gavión Hiperbóreo

Taxonomy. *Larus hyperboreus* Gunnerus, 1767, northern Norway.
Variously considered monotypic or polytypic; subspecific distinctions subtle. Race *leuceretes* sometimes merged into nominate race. *Larus glaucus* is a synonym for *L. canus*. Four subspecies normally recognized.
Subspecies and Distribution.
L. h. hyperboreus Gunnerus, 1767 - Jan Mayen and Spitsbergen E to Taymyr Peninsula.
L. h. pallidissimus Portenko, 1939 - Taymyr Peninsula E to Bering Sea, including Pribilof Is.
L. h. barrovianus Ridgway, 1886 - Alaska to W Canada (NW Mackenzie region).
L. h. leuceretes Schleep, 1819 - E Mackenzie region through N Canadian archipelago to Greenland and Iceland.
Winters S to CW Europe, Japan and CW & CE USA.



Descriptive notes. 64-77 cm; 1070-1820 g; wingspan 132-142 cm. One of the largest gulls; plumage all white, except for pale grey mantle and upperwings; all flight-feathers tipped white; bill yellow, with red gonydeal spot; legs pinkish; iris pale yellow, with red orbital ring. Similar to *L. glaucoides* but larger; appears heavier-bodied and proportionately shorter-winged. Has shorter wing, heavier bill and paler mantle than *L. argentatus*, and lacks dark markings on primary tips. Non-breeding adult streaked brown from head to upper breast. Juvenile pale brown below, and white above with variable and extensive pale brown scaling; wingtips whitish to pale tan. 1st-winter mottled greyish-buff; bill pink, with well defined black tip. Older immature nearly immaculate white, with some dusky brown flecks and bars. Races differ in size and in tone of mantle, but much individual variation; *barrovianus* smallest and darkest. Hybrids with *L. glaucescens* common in W Alaska (in Seward Peninsula, over 50% of birds), showing dark iris and grey on primary tips. Many birds in S Iceland appear to be hybrids with *L. argentatus*, although opinions on this differ.
Habitat. Coasts, bays, harbours, landfill sites and fishing wharves; rarely large inland lakes. Breeds on cliffs in Arctic and subarctic, mainly coastal or a few kilometres inland, particularly near human settlements, and often near gull or goose colonies; also on islands offshore or in lakes.
Food and Feeding. Fish, molluscs, crustaceans, rodents, birds, eggs and young of birds (especially ducks, auks, shorebirds), insects, berries, carrion, refuse and offal. In Iceland, consumes blue mussel (*Mytilus edulis*), *Littorina palliata*, crabs (*Hyas*), sea-urchins and sandeels (*Ammodytes*). At Barrow, Alaska, feeds on fish, on minute crustaceans in surf, and on offal and refuse; gathers at whale corpses. Inland breeders rely heavily on birds, but also take fish from rivers. In winter, southernmost birds feed mainly at rubbish dumps, behind ships, at sewage outfalls, and on fish offal; also exploit spawning squid, pelagic crabs, mammal carcasses, and occasionally faeces of marine mammals. Piratic on other gulls and skuas. Scavenges in intertidal zone.
Breeding. Synchronous laying mid-May to mid-Jun, depending on latitude and ice conditions; strong selection for early nesting because of short season. Solitary or in small colonies. Many non-breeders around nesting areas in W Alaska. Nest is a pile of seaweed and debris, often lined; usually on edge of cliff, rock pinnacle, sometimes on slope. 2-3 eggs (mean 2·88 in W Alaska); incubation 26-30 days; chick similar to that of *L. marinus*, but paler, greyer, with markings more obscure; chick phase 40 days (fledging reported as c. 49 days in Spitsbergen); most young apparently independent by early Sept.
Movements. Partially migratory. Winters from edge of ice to N USA, N Europe and Japan, casually further S. W Palearctic birds remain in breeding range, moving S ahead of ice. E Siberian birds winter on coasts of E Asia S to Japan. Alaskan breeders winter from Aleutians to California. Those breeding in E Canada winter sparingly to Middle Atlantic States. Adults leave Greenland in early Sept, while young linger until freeze-up. In some winters, occurs in S in larger numbers than usual.
Status and Conservation. Not globally threatened. Total population probably over 100,000 pairs. W Palearctic holds c. 20,000 pairs, with 50% on Spitsbergen; E Palearctic 10,000-50,000 pairs. Estimated Alaskan population at least 15,000 pairs at thousands of sites; abundant at Barrow. Greenland holds at least 10,000 and possibly closer to 100,000 pairs. Is being displaced by *L. argentatus* in some areas, e.g. S Iceland; decreasing in Greenland.
Bibliography. Andresen & Thomas (1986), Armstrong (1983), Brazil (1991), Cramp & Simmons (1983), Drury (1984), Etchécopar & Hüe (1978), Evans (1984a, 1984b), Gaston (1991), Guðmundsson (1955), Helms (1926), Howell & Webb (1995a), Hume (1975), Ilicev & Zubakin (1988), Ingolfsson (1970a, 1970b, 1976), Jacob & Lardinois (1982), Kay (1947), Knystautas (1993), Kondratiev (1991), Lensink (1984), Parmelee & MacDonald (1960), Perennou *et al.* (1994), Richards (1990), Rogacheva (1992), Root (1988), Salomonsen (1967b), Spear (1987), Stempniewicz (1983), Strang, C.A. (1974, 1977), Tasker *et al.* (1987), Urban *et al.* (1986).

20. **Iceland Gull**

Larus glaucoides

French: Goéland arctique **German**: Polarmöwe **Spanish**: Gaviota Groenlandesa
Other common names: Greenland Gull; Kumlien's Gull (*kumlieni*)

Taxonomy. *Larus glaucoides* B. Meyer, 1822, Iceland.
Formerly listed as *L. leucopterus*. Closely related to *L. argentatus*, and sometimes treated as conspecific. Form *kumlieni* sometimes considered a separate species, as birds with grey wingtips occur alongside those with white wingtips in Nearctic. E-W cline apparent, from pale *glaucoides* to slightly darker *kumlieni* to darker *L. thayeri*. Increasing tendency to lump *L. thayeri* with *L. glaucoides* refuted, as such treatment would make the species undiagnosable; yet *kumlieni* hybridizes with *L. thayeri*, and may be closer to latter than to *L. g. glaucoides*. Two subspecies provsionally recognized.
Subspecies and Distribution.
L. g. kumlieni Brewster, 1883 - NE Canada, on Baffin I and NW Ungava; winters from Labrador S to E Great Lakes and Virginia.
L. g. glaucoides B. Meyer, 1822 - S & W Greenland; winters S to N Europe.
Descriptive notes. 55-64 cm; 557-863 g; wingspan 125-130 cm. Medium-large, long-winged gull, all white but for pale grey mantle, upperwing-coverts and flight-feather bases; bill yellow, with red gonydeal spot; legs pink; iris yellow, with red orbital ring. Plumage pattern similar to that of larger *L. hyperboreus*, but bill shorter and more slender; at rest, wingtips extend well past tail; has more buoyant flight. Smaller than many *L. argentatus* (though size range overlaps), generally more gracile, and lacks black on primaries. Non-breeding adult streaked brownish on head to upper breast. Juvenile and 1st-winter plumage very pale, more uniform than in *L. hyperboreus*, head sometimes dusky, and tail with pale grey terminal band; bill dusky brownish to brownish horn (may seem black at distance), and usually paler at base than distal half, though not so sharply demarcated as in *L. hyperboreus*. Slightly larger-billed race *kumlieni*, with darker red orbital ring and dark iris, has pale grey outer webs to outer primaries 10 and 9, as well as grey tips to primaries 8 and 7, but highly variable (some individuals in

kumlieni colonies have all white wingtips, some have nearly uniform pale grey primaries); immature shows darker primaries and is less barred than in nominate race. Hybrid *L. argentatus* x *L. hyperboreus* (formerly identified as "*L. nelsoni*") very similar to *kumlieni*, but larger, with heavier bill.

Habitat. Rocky coasts and fjords of low Arctic, breeding on steep cliffs, offshore stacks, sometimes undisturbed low islands. In winter also occurs in harbours, occasionally rubbish dumps, and rarely inland reservoirs, but normally shuns fresh water.

Food and Feeding. Mainly small fish, e.g. salmon (*Salmo*), sprat (*Sprattus*), herring (*Clupea*), as well as marine invertebrates; eggs and chicks of various birds; seeds and fruits sometimes important. Scavenges in intertidal zone; feeds on stranded carcasses. Some individuals specialize on *Rissa tridactyla* colonies, hunting for unguarded eggs and chicks. Wintering birds likely to exploit rubbish dumps and sewage outfalls. Feeds mainly from the water surface, but also by plunge-diving; picks from ground.

Breeding. Lays mid-May to mid-Jun in Greenland. Solitary or in small colonies. On cliff ledge, occasionally on ground. Prefers steep cliffs over 100 m in height. In mixed colonies with *R. tridactyla*, tends to nest higher on cliffs, preferring broader ledges; in Greenland often nests with *L. hyperboreus*. Cliff-nesting individuals reported to behave more like *Rissa*, ground-nesters more like *L. argentatus*. Nest of seaweed and dry grass. 2-3 eggs; incubation and fledging periods not documented; chick undescribed. Chicks preferentially do not face cliff wall; not recognized by adults until c. 19 days. Chicks from cliff nests do not run or jump when disturbed, while those from ground nests run. Young fledge in late Jul, and move with adults to coastal feeding areas.

Movements. Northernmost populations migratory; populations of S Greenland resident. Post-breeding birds linger around colony areas into Aug or Sept. Young disperse more widely than adults. Birds from E Greenland more migratory than those in W Greenland, the latter moving mainly from inland fjords to coast after breeding, and dispersing mainly along coast in winter. Some Greenland birds disperse to North America, most to Iceland and Faeroes, fewer to NW Europe. Those from E Greenland move mainly to Iceland, where species is very common in winter. Birds from Baffin I move S to Hudson Bay, and thence to the Maritime Provinces, wintering sparsely from Labrador to E Greak Lakes and Virginia. Most birds reaching New England, Middle Atlantic states and N & NW Europe are juveniles; they usually associate with *L. argentatus* in harbours and at rubbish dumps. Numbers reaching S areas vary anually.

Status and Conservation. Not globally threatened. Population figures insufficiently known. Greenland population estimated at 10,000-100,000 pairs, but world total (including *kumlieni*) may number under 100,000 pairs. Only a minute portion of the population filters down to Europe and North America, where ornithologists might assess trends. No adequate studies on breeding grounds. No reason to assume that numbers are declining, although increased non-native predators pose a hazard to many Arctic and subarctic species. In Greenland the local inhabitants hunt present species extensively, and may harvest 23% of population annually.

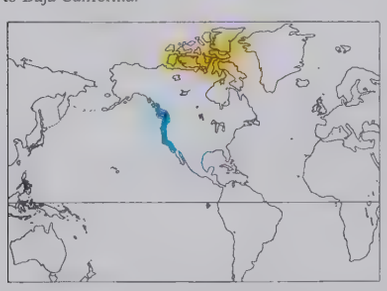
21. Thayer's Gull



Larus thayeri

French: Goéland de Thayer **German**: Thayermöwe **Spanish**: Gaviota Esquimal

Taxonomy. *Larus thayeri* W. S. Brooks, 1915, Banks Island.

A highly controversial and variable taxon, alternatively treated as a race of *L. argentatus* or of *L. glaucoides*. Interbreeds with *L. g. kumlieni* in N Hudson Bay and E Baffin I, prompting some to treat it as a race of *L. glaucoides*. Although seemingly random pairing occurred in N Hudson Bay, a deficit of intermediate plumages suggested that post-mating isolation may exist. Pending further hybridization studies, *thayeri* is best treated as a discrete species. Merging it with *L. glaucoides* would make latter species undefinable; moreover, other species frequently hybridize in some localities (e.g. *L. occidentalis* and *L. glaucescens*), and consistency would demand that they also be merged. Monotypic.

Distribution. N Canada, from Banks I E to N Hudson Bay and N Baffin I (E to vicinity of Home Bay), N through Ellesmere I to W Greenland (near Thule). Winters on Pacific coast, from British Columbia to Baja California.

Descriptive notes. 56-63 cm; 846-1152 g; wingspan 130-140 cm. White-headed gull with pale grey mantle and upperwings; bill yellow, with red gonydeal spot; legs pinkish; iris dark brown to yellow, with purplish orbital ring. In all plumages very similar to *L. argentatus*, but slightly smaller, and usually with slaty black rather than black on upper surface of primaries; wingtips usually mostly white below, with slightly greyer "tongues"; mantle sometimes lighter, but on many birds somewhat darker; feet a deeper pink, sometimes purplish; bill more slender than in *L. argentatus*, with gently curving culmen and less prominent gonydeal angle. Iris colour ranges from dark brown in SE to yellow with brown flecks in far N. Specimens from Bylot I had ivory-yellow iris heavily speckled with black, and mottled yellow-and-pink eyelids; olive-ochre bill, becoming olive-buff at tip. Very difficult to distinguish from some *L. glaucescens* or *L. argentatus*, however, and from the more numerous hybrids that winter on Pacific coast of North America. Most constant features are rounded head, and bill shape.

Habitat. Coasts of rocky islands, feeding also around fishing piers, rubbish dumps, and settlements; breeds mainly on coastal cliffs.

Food and Feeding. Diverse diet. Inadequately studied on breeding grounds; non-breeders feed on refuse and scraps, offal, and animal debris around settlements. In winter, takes fish, marine invertebrates and offal; follows fishing boats with other gulls.

Breeding. Essentially unrecorded. Lays in early Jun. Small colonies of up to a few dozen pairs. Mainly on cliffs, usually with *L. hyperboreus*, nesting below the larger species; requires ledges about 3 x larger (mean 920 cm²) than those used by *R. tridactyla*; rarely on ground. Gathers nest material away from colony; guards nest-site aggressively before laying. Reported to build larger nest cup than ground-nesting gulls, but does not incorporate mud; many first eggs roll off ledges. Usual clutch size unknown, probably 2-3 eggs; incubation and fledging periods not documented; chick said to be darker and greyer than *L. argentatus*, with finer spotting, and more white on underparts, but probably just as variable as latter, and indistinguishable. Chicks preferentially do not face cliff wall; reported not to pump head while begging; not recognized by adults until c. 19 days. Chicks of cliff-nesting pairs do not run or jump when disturbed, while those from ground nests run.

Movements. Migrates S and W, some reaching North Slope and Pacific coast at Alaska, others (mainly juveniles) moving into Chukchi Sea, then moving S. Winters from British Columbia to Baja California, with birds arriving in Oct; 1st-year birds move further S. Numbers detected along Pacific coast, however, are hardly sufficient to account for the large numbers which may breed in Arctic Canada. Species very rare in the Maritime Provinces and NE USA, being accidental in most states. Presumably still overlooked in many areas.

Status and Conservation. Not globally threatened. Status and trends insufficiently known, but species probably secure. Very few breeding sites have been studied. Christmas Bird Counts locate c. 20,000 individuals, mainly along Pacific coast. Apparently widely distributed in NE Canadian Arctic, nesting in small colonies on cliffs.

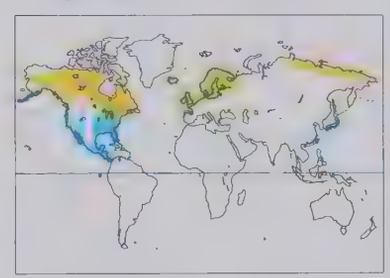
22. Herring Gull

Larus argentatus

French: Goéland argenté **German**: Silbermöwe **Spanish**: Gaviota Argéntea

Taxonomy. *Larus Argentatus* Pontoppidan, 1763, Denmark.

Systematics of present species and its close relatives represent one of the most complex challenges in ornithology, and typify the discord between evolution, biogeography, reproductive isolation, and taxonomy. The closely related taxa were often treated as a ring of subtle races, until the two extremes (*L. argentatus*, *L. fuscus*) met in W Europe and did not freely interbreed. Many forms are now treated as separate species, since it is uncertain how to apply the biological species concept to the complex pattern of variation and interbreeding. Present species is reported to hybridize extensively with *L. hyperboreus* in Iceland (but this disputed), with *L. glaucescens* in Alaska, but rarely with *L. fuscus* in Europe. Confusion prevails over the species boundaries of *L. argentatus*, *L. cachinnans* and *L. fuscus*, with many of the identifiable races assigned at one time or another to 2 or even 3 of these species. The most extreme lumping has included *L. glaucoides*, *L. fuscus* and even *L. californicus* within *L. argentatus*; a more traditional treatment includes *L. cachinnans* and *L. armenicus*. Owing to sympatry without hybridization in W France, *L. cachinnans* is now seen as a distinct species, further supported by molecular evidence. Much controversy surrounds the form "*omissus*" of the N Baltic region, with pink-legged individuals in a (formerly) predominantly yellow-legged population: it has been treated as a race either of *L. argentatus* or of *L. cachinnans*, but it is probably simply a morph of *L. argentatus* (based mainly on voice and primary pattern). Bluish-legged birds of Russian Arctic islands included in *vegae*, but sometimes separated as *birulae*. See also *L. cachinnans*, *L. armenicus*, *L. fuscus*. Four subspecies recognized.



Subspecies and Distribution.

L. a. smithsonianus Coues, 1862 - North America; winters S to Central America.

L. a. argenteus C. L. Brehm, 1822 - Iceland, Faeroes, British Is and W France to W Germany; winters S to N Iberia.

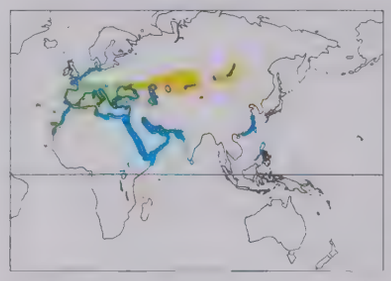
L. a. argentatus Pontoppidan, 1763 - Denmark and Fenno-Scandia, to E Kola Peninsula; winters mostly in N & W Europe.

L. a. vegae Palmén, 1887 - NE Siberia; winters S to China.

Descriptive notes. 55-67 cm; 720-1500 g; wingspan 135-145 cm. Large gull with powerful bill; white head, underparts and tail, with grey upperwings and mantle (varying from pale to dark grey), and black wingtips with a white-spotted pattern; bill yellow, with red gonydeal spot; legs and feet pink (yellowish on some N Baltic birds); iris pale yellow, with orange to yellowish red orbital ring. Differs from *L. cachinnans* in pink legs. Non-breeding adult has dark-streaked head and neck, and duller bill and orbital ring. Juvenile varies with race, but basically grey-brown with pale spots, and blackish primaries and tail feathers; full adult plumage not achieved until 4 years. Races differ mainly in size, in tone of mantle and upperwing, and in exact pattern of primary tips, but quite variable; even within Netherlands (*argenteus*) mantle colour varies among colonies from light to dark grey, and the darkest-mantled birds from Norway (nominate *argentatus*) are comparable to the lightest-mantled *L. fuscus graellsii* from Britain; NE Asian *vegae* is large, heavy-billed, with a darker mantle, and a heavily spotted head in winter; *argenteus* generally smallest and palest, *smithsonianus* intermediate between *argenteus* and nominate. Minimal hybridization with *L. fuscus*; offspring have lower survival than either parental type.

Habitat. Mainly coastal and near-coastal areas; also inland, at large lakes and reservoirs, on fields and at rubbish dumps; sometimes at sea. Breeding habitats very varied: coastal cliffs and stacks, rocky and grassy islands, sandy beaches, gravel bars, salt-marshes, limestone outcrops, and buildings; exploits man-altered habitats such as clay pits.

Food and Feeding. Omnivorous and highly opportunistic, exploiting superabundant food when available; spans the full range of gull dietary items and feeding behaviour; powerful predator. Feeds extensively on fish, earthworms, crabs, and other marine invertebrates (molluscs, starfish), taken alive or found dead; fish and molluscs can comprise 60-70% of diet. On tidal flats in Maine (NE USA), preferentially selected large ragworms (*Nereis virens*) over smaller worms, and blue mussels (*Mytilus edulis*) and crabs (*Cancer maenas*, *C. irroratus*). Huge numbers scavenge at rubbish dumps, fishing wharves and sewage outfalls; frequently follows fishing boats. Preys on birds, bird eggs and young, and rodents, some individuals specializing on these items; flocks sometimes prey on fatigued migrant passerines, particularly those struggling to land into a wind. Takes insects, including ants; sometimes gorges on berries, even bayberry (*Myrica pennsylvanica*), or on turnips. Feeding methods very varied, include walking on mudflats, plunge-diving and surface-dipping; less likely than the smaller gulls to engage in aerial hawking; occasionally foot-paddles on mud, grass or in shallow water. Routinely



drops bivalves onto hard surface to crack them; immatures do so less often, and less successfully. Catches small mammals and birds by stalking and ambushing them.
Breeding. Lays from early May to early Jun (rarely late Apr) in NE USA and NW Europe; early May in Murmansk; average dates earlier as colonies age. Colonies of dozens to thousands of pairs; occasionally solitary, or as single pairs on edge of other seabird colonies. With increased population, density in some colonies rose from 30 pairs/ha to 100 pairs/ha, and aggression and cannibalism increased. In Newfoundland, rocky marine terraces had highest density and highest productivity, while nests in grassy meadows suffered higher predation. Nearest-neighbour distances range from 0·6 to 10 m, but usually over 2 m. Shows high philopatry to natal colonies. Bulky nest of grass and vines, on ground, cliff ledge or roof, usually sheltered in vegetation. Usually 2-3 eggs (1-5, mean 1·7-2·8); incubation 28-30 days; chick buff-grey above with large blackish spots, well defined on head, buffy white below, with black throat spot; hatching weight c. 49-66 g (Barents Sea); fledging c. 40-45 days, independent c. 1-2 weeks later. Chick growth rate declined as population density increased. Pairs in which mates contribute equally have greater success. Main egg and chick losses due to predation by conspecifics and other gulls. First breeding at 3-7 years, usually 5 years. Recorded longevity of 32 years.
Movements N birds are migratory, and may leapfrog over S breeders. Winters as far S as West Indies and Central America, but in Palearctic usually only to Iberia. Finnish breeders move short distances, most remaining in Baltic; many N European birds winter in S North Sea. Some of those breeding in NE Asia remain well N in winter, but many migrate, wintering as far S as coasts of South China Sea; some post-breeding wandering to N Alaskan coast.
Status and Conservation. Not globally threatened. One of the most abundant coastal birds in North America and Europe. Centre of abundance is in Norway. At least 1,000,000 pairs breed in the Palearctic, including 206,000 in British Is; over 150,000 in E North America. With the enforcement of protection from persecution and egging, and aided by the availability of refuse and other food items to diminish juvenile mortality, a massive and dramatic growth in numbers has taken place throughout its range. Populations expanded greatly from 1910 to 1975, but have stabilized in most places, or the rate of increase has slowed down. Species colonized Iceland only in 1925, and increased steadily until 1940. In Britain, population grew at annual rate of 12·8% during period 1930-1978, with colonization of moorlands and development of roof-nesting. In Nearctic, New England population increased from 11,000 to 90,000 pairs from 1901 to 1972. On Long I, New York, numbers peaked in mid-1970's with 20,000 pairs, and have actually declined since with 14,800 pairs in 1983; egging has increased to serious proportions. Pollutant levels in eggs at Great Lakes declined steadily until early 1980's, before levelling off. Species is regarded as a pest and a threat to many other colonial species, as it usurps their habitat and preys upon their eggs and young; preventative measures are frequently taken. Often considered hazardous at airports, and control efforts are frequently introduced.

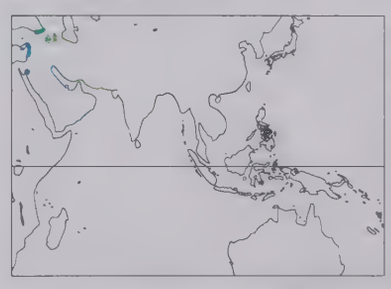
23. Yellow-legged Gull

Larus cachinnans

French: Goéland leucophée **German**: Weißkopfmöwe **Spanish**: Gaviota Patiamarilla

Taxonomy. *Larus cachinnans* Pallas, 1811, Caspian Sea.
All subspecies listed below have often been treated under *L. argentatus*. Some earlier authors emphasized the view that *L. cachinnans* was a separate species; now widely accepted as such, based on sympatry with *L. argentatus* in W France, and on behaviour and morphology. Molecular data also show it to be a distinct species, closer to *L. fuscus*, suggesting that the three species may have diverged during the Pleistocene. The form "*ponticus*" of the Caspian Sea is a synonym of nominate *cachinnans*. See also *L. argentatus*. Five subspecies recognized.
Subspecies and Distribution.
L. c. atlantis Dwight, 1922 - Azores to Madeira and Canary Is.
L. c. michahellis J. F. Naumann, 1840 - W & S Europe and NW Africa E through Mediterranean.
L. c. cachinnans Pallas, 1811 - Black Sea to Caspian Sea and E Kazakhstan; winters S to SW Asia, Middle East and NE Africa.
L. c. barabensis Johansen, 1960 - C Asian steppes; winters mostly in SW Asia.
L. c. mongolicus Sushkin, 1925 - SE Altai and L Baikal to Mongolia; winters mostly in S Asia.
Descriptive notes. 58-68 cm; 800-1500 g; wingspan 140-155 cm. Large white-headed, white-bodied gull, with grey mantle and upperwings, and black and white wingtips; bill deep yellow, with large bright red gonydeal spot; legs yellow; iris pale yellow, with conspicuous red orbital ring. Distinguished from *L. argentatus* by yellow legs, vermilion orbital ring, blacker primaries, and slightly darker mantle. Non-breeding adult has unstreaked white head, unlike *L. argentatus* and *L. fuscus*. In some *L. cachinnans* populations (NW Spain), however, 5-10% of birds have pink or partly pink legs, despite the claim that yellow leg colour is a universal characteristic of this species. 1st-winter bird usually paler below and on head than that of *L. argentatus*; immature has a black subterminal mark on



the bill, which occasionally persists in adult plumage. Races differ in size, in tone of mantle, and in amount of black in primaries, but variable; race *atlantis* smaller, with darker mantle.
Habitat. Coasts and inland habitats. In W Europe, largely confined to coastal regions, but locally also rivers and inland lakes; in C Asia inhabits lakes in steppe and semi-desert. Also feeds at rubbish dumps, fields, and various other terrestrial habitats. Breeds on rocky and sandy islands, beaches, cliffs, spits, and grassy or shrubby river islands; in flooded areas may nest on bushes; at Black and Caspian Seas nests mainly on islands, ranging from barren to well vegetated.
Food and Feeding. Mostly fish, invertebrates, mammals, refuse, scraps, offal, bird eggs and chicks, and insects. Off Morocco, breeding birds fed on refuse, fish, insects, molluscs and a lizard, but fed their chicks mainly fish. At Caspian Sea sometimes feeds chicks mainly on mole-crickets (*Gryllotalpa*). In some Caspian Sea colonies, main prey is susliks (*Spermophilus*, up to 140 g) and other small rodents, obtained in surrounding steppes; also insects (particularly beetles), with fish only 7% of food items. In Crimea mostly susliks and voles (*Microtus*), but in some colonies mainly fish and crustaceans, and in others preys heavily on eggs and chicks of gulls (conspecifics, as well as *L. melanocephalus*, *L. genei* and even *L. ichthyaetus*). Exploits human intrusion, seizing eggs when incubating birds flushed. Some adults obtain food mainly by following fishing boats and taking offal. In Selvagen Is (N of Canary Is) flies inland to feed on grasshoppers and moths. Kleptoparasitic on *L. audouinii*, particularly when fishing vessels not active. Forages mostly by wading in intertidal zone, plunge-diving, and following ships; also follows plough.
Breeding. Similar to *L. argentatus*. In some colonies, territorial throughout winter; lays from mid-Mar. Colonies of up to c. 8000 pairs (Medes Is, NE Spain); forms monospecific clusters, even when nesting beside other gulls; sometimes on high ground, hundreds of metres from water. Nests preferentially close to or under bushes, sometimes in bushes or dense copses of osier (*Cornus*); on rooftops in several cities, e.g. Barcelona (Spain). Density 20-140 nests/ha, usually a few metres apart. Nest made of nearby vegetation, feathers, debris and old carcasses; often builds or lines nest with eelgrass (*Zostera marina*). Usually 2-3 eggs (1-4, mean 2·68 at Volga Delta); incubation averages 26-29 days; chick similar to that of *L. argentatus*; hatching weight c. 60 g; swims at c. 10 days, when partly feathered; fledging c. 6-7 weeks.
Movements. Many populations sedentary or slightly dispersive. E population (*mongolicus*) migrates to China and India. Birds from Balkans disperse locally as far as R Danube. French and Spanish breeders disperse overland to Atlantic and E along Mediterranean. Birds from N Africa disperse around Mediterranean. In recent years, increasing numbers of birds breeding in SW Europe and the Mediterranean have moved N after breeding, fair numbers now spending the winter in SE England and S coasts of North Sea.
Status and Conservation. Not globally threatened. Overall status uncertain, owing to treatment as conspecific with *L. argentatus* until relatively recently. Mediterranean populations have increased during 20th century, but still number under 100,000 pairs. On Chafarinas Is (off NE Morocco) one colony increased from 250 pairs in 1976 to 850 pairs in 1985, while a second totalled 3000 pairs. Over 6500 pairs of race *atlantis* breed in Macaronesia. In Black Sea area many nests were destroyed and adults shot during 1940's, to reduce their predation on the "beneficial" *L. melanocephalus*. Culling is also considered to protect *L. audouinii* from expanding *L. cachinnans* populations; has taken place in parts of Spain. A frequent victim of oil pollution in some areas (e.g. Azerbaijan). Many colonies, especially in E of range, are regularly robbed of eggs by local human communities.

24. Armenian Gull

Larus armenicus

French: Goéland d'Arménie **German**: Armenienmöwe **Spanish**: Gaviota Armenia

Taxonomy. *Larus armenicus* Buturlin, 1934, Lake Sevan, Armenia.
Historically treated as a race of *L. argentatus*, but smaller, with shorter bill; black band across both mandibles diagnostic, but not mentioned in original description. Also has a delayed moult. Monotypic.
Distribution. Caucasus through Armenia to E Turkey and NW Iran. Winters in SE Black Sea, E Mediterranean and N Red Sea.

Descriptive notes. 57-60 cm; 950-1050 g; wingspan c. 140 cm. White-headed gull with grey mantle and upperwings; bill deep yellow, with narrow subterminal black band, and red spot near gonys; legs yellow to orange-yellow, brighter than in *L. cachinnans*; iris mainly yellowish to brown, with red orbital ring. Upperparts slightly paler than in *L. fuscus heuglini*, but darker than in *L. argentatus argenteus*. Distinguished from *L. argentatus* by wing pattern, bill, yellow legs, and darker eyes. Compared with both *L. argentatus* and *L. cachinnans*, has more extensive black at wingtips, with a large triangle from outer primary to primary 7, and more extensive black as far as primary 3; primaries have small white tips, with a small white subterminal window on outer primary. Despite much individual variation, present species and *L. cachinnans* show

subtle differences in size and appearance: present species is smaller, more slender, with a shorter, stubbier bill, and more rounded forecrown and hindcrown (*L. cachinnans* has flatter, more angular head); grey base to secondaries forms a subterminal band on underwing. Post-breeding adult has a smudged appearance to bill, often with both red and black markings ill-defined; by winter, bill is deep yellow, with a sharp black subterminal band that covers the red spot, and creamy yellow tip; some non-breeding adults have fine streaking on crown and sides of head, and coarser streaking on nape, which is more extensive than in *L. cachinnans*, but less than in *L. argentatus* or *L. f. heuglini*. Juvenile and 1st-winter birds have all black bill. 2nd-winter has white head with faint streaking on face, and stronger markings on hindneck which may suggest a faint collar; bill sometimes all black, but usually with distal half dark and base pale (sometimes yellow). By 3rd winter, head is white with dark markings on hindneck.

Habitat. Inland and coastal waters. Breeds only at mountain lakes, using reedbeds, beaches, and agricultural fields; at L Sevan (Armenia), at altitude of 1900 m, now confined to small islands.

Food and Feeding. Very inadequately studied. Presumably feeds on fish, invertebrates and offal.

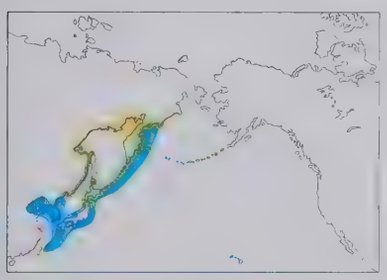
Breeding. Lays from late Apr. Only 2 colonies known, with nests 1-2 m apart in densest areas; among stones and grass or under bushes. Species is quite tolerant of intruders. Long-call display usually accompanied by complete upward head-toss, as in *L. fuscus*; frequently displays with wings held slightly outwards and lowered. Usual clutch 3 eggs. No further information available.

Movements. Some birds remain in the breeding area all year, but many migrate short distances. Winters in Black Sea, and in E Mediterranean from Turkey to Israel, where it co-occurs with *L. cachinnans*; many winter S at least to Tel Aviv, with few reaching N Red Sea. Only a vagrant to Persian Gulf.

Status and Conservation. Not globally threatened. Probably requires reclassification as Vulnerable, due to very low numbers and minute range. No published censuses available; possibly numbers fewer than 10,000 pairs. Very few studies have been carried out on present species, presumably in part because until recently it was widely regarded as merely a subspecies of *L. argentatus*. Severe decrease from 1930's to 1960's, when gulls were persecuted because of damage to fisheries, and eggs were harvested for food. At L Sevan only 60-100 pairs in 1970's, but 4000 pairs in 1990; this area now forms Sevan National Park. The other known Armenian colony is at Arpilich L, where more than 4000 pairs breed.

Bibliography. Beaman (1994), Bertault *et al.* (1988), Bourne, W.R.P. (1993a), Buturlin (1934), Buzun (1993), Cramp & Simmons (1983), Dubois (1985), Filchagov (1993), Géroudet (1982), Ginn *et al.* (1989), Hollom *et al.* (1988), Hüe & Étchécopar (1970), Madge (1990), Richardson, C. (1990), Satat & Laird (1992), Voous (1959).

25. Slaty-backed Gull



Larus schistisagus

French: Goéland à manteau ardoisé **German**: Kamtschatkamöwe **Spanish**: Gaviota de Kamchatka
Other common names: Pacific Gull, Kamchatka Gull

Taxonomy. *Larus schistisagus* Stejneger, 1884, Kamchatka.

Considered closely related to *L. genei* by some authors, to *L. argentatus* (with which it occasionally hybridizes) by others, but appears to be a distinctive N Pacific species. Monotypic.

Distribution. NE Siberia, from Cape Navarin and Kamchatka S to Hokkaido, NE Honshu and Vladivostok. Winters S to Taiwan.

Descriptive notes. 55-67 cm; 1050-1695 g; wingspan 132-148 cm. Typical large, white-headed, dark-mantled species, with slightly greater sexual size dimorphism than in most gulls; head heavy, with peak well behind eye, giving a flat sloping forehead and crown, and a steeply sloping hindcrown; usual mantle colour dark slaty grey, somewhat paler than in *L. marinus*, but highly variable, ranging all the way to pale grey; primaries black, with very extensive white windows and tips in outer primaries; underwing with extensively slaty, black-tipped primaries, contrasting with pale underwing-coverts; relatively short but stout bill yellow, with red gonydeal spot; legs dark pink to almost reddish pink; iris yellow, with pink to purple orbital ring. Distinguished by its angular head, bright pink legs, and dark primaries below, with heavy bill proportionately deeper than in *L. argentatus*. Non-breeding adult has dusky streaking on head and neck. Immature very similar to that of *L. argentatus*.

Habitat. Inshore coastal waters; breeds on low sea cliffs, rocky islets, sandy shores, or rocky tops of sea cliffs.

Food and Feeding. Varies from year to year, depending on availability. Mainly fish and invertebrates (e.g. crabs, sea urchins), also carrion, refuse, offal, bird eggs and chicks; occasionally voles and insects. During salmon-spawning, flies upriver to feed on fish and roe; takes leftovers from bear-kills; eats berries in late summer; in winter, exploits waste from fisheries and slaughterhouses. Some Hokkaido males specialize on predation, piracy and scavenging in seabird colonies, taking adult and young alcids and *L. crassirostris* chicks, but they feed their chicks mostly fish (80%); on Teuri I (N Japan) has heavy impact on *L. crassirostris*, particularly late in season. Foods utilized varied from colony to colony on Hokkaido, with sardines (*Sardinops melanosticta*), rock fish (*Sebastes*), sandeels (*Ammodytes*) and seabirds in different proportions, depending on year; with crash of sardine stocks, took more birds, sandeels and refuse. In Sea of Okhotsk eats mainly adult seabirds, eggs and chicks, taking disproportionate numbers of murrelets (*Brachyramphus*), *Rissa tridactyla*, and Parakeet Auklets (*Cyclorrhynchus psittacula*). Uses variety of foraging methods, including plunge-diving and surface-plunging.

Breeding. Arrives Apr in S, early Jun in Sea of Okhotsk; lays from late May in S to early Jun in N. Colonies of dozens to 1500 pairs on low riverine islands, sloping clifftops, and cliff ledges; density often 2 nests/m², but more sparse on slopes. Nest of grass, seaweed and feathers, often placed in dense vegetation or among boulders, frequently close to cliff face. Usually 3 eggs (1-4); incubation 28-30 days, on Kuril Is 31-33 days; chick grey-brown, spotted black above, on breast, and more distinctly on head, with white belly; fed by parents for 40-45 days. Productivity greater among pairs exploiting seabird chicks to feed their young.

Movements. Many populations non-migratory, dispersing into Bering Sea and Sea of Japan; some migrate S towards coast of China. Non-breeding and wintering birds reach Alaska. Winters from Bering Sea to Japan and Taiwan; occurs casually on coasts of China in winter.

Status and Conservation. Not globally threatened. Total population c. 100,000 pairs. Estimates for Kamchatka population range from 47,000 pairs in more than 200 colonies, to 110,000 pairs. Largest colony (1500 pairs) on Ptichem I, off Karaginskiy I (NE Kamchatka). Hokkaido population small, but increasing by perhaps as much as 19% per year in some colonies.

Bibliography. Armstrong (1983), Austin & Kuroda (1953), Beaman (1994), Brazil (1991), Drury (1984), Étchécopar & Hüe (1978), Firsova (1986), Firsova *et al.* (1982), Flint *et al.* (1984), Goetz *et al.* (1986), Gustafson & Peterjohn (1994), Hasegawa (1984), Hashimoto (1977), Ilicev & Zubakin (1988), Knystautas (1993), Kondratiev (1991), Kondratyva (1994), Litvinenko (1986), Perennou *et al.* (1994), Portenko (1963), Velizhanin (1977), Vyatkin (1986), Watanuki (1982, 1983, 1988a, 1988b, 1989, 1992), Watanuki *et al.* (1988).

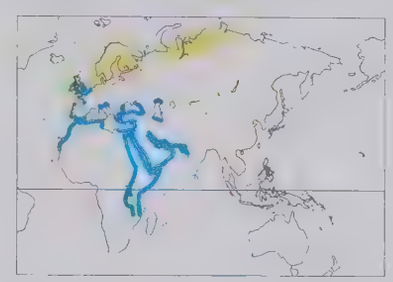
26. Lesser Black-backed Gull

Larus fuscus

French: Goéland brun **German**: Heringsmöwe **Spanish**: Gaviota Sombría

Taxonomy. *Larus fuscus* Linnaeus, 1758, Sweden.

Closely related to *L. argentatus*, and sometimes considered conspecific, but in most areas of sympatry the two are reproductively isolated; molecular evidence separates present species from *L. argentatus* and *L. cachinnans*. Very complex systematics involving several of the races. Some evidence that *heuglini* overlaps nominate *fuscus*, perhaps without interbreeding; may merit specific status as *L. heuglini*, which may even include *L. a vegae*. Form described as "*antelius*" (W Siberia) is a synonym of *heuglini*; "*taimyrensis*" (Yenisey and Taymyr Peninsula) considered not separable from *heuglini*. See also *L. argentatus*. Four subspecies recognized.



Subspecies and Distribution.

L. f. graellsii A. E. Brehm, 1857 - Iceland, Faeroes, British Is, France and Iberia; winters from SW Europe to W Africa.

L. f. fuscus Linnaeus, 1758 - Sweden and N Norway E to White Sea; winters mostly in Africa and SW Asia.

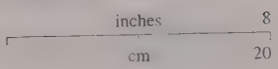
L. f. intermedius Schiøler, 1922 - Netherlands, Denmark and S Norway, with isolated population in NE Spain (Ebro Delta); winters mostly in W Europe and W Africa.

L. f. heuglini Bree, 1876 - N Siberia, from S Kola Peninsula E to Taymyr Peninsula; winters from Middle East S to E Africa, and E to NW India.

Descriptive notes. 51-61 cm; 550-1200 g; wingspan 124-127 cm. Medium-sized, dark-mantled, yellow-legged gull; bill yellow, with red gonydeal spot; iris yellow, with red orbital ring. Much smaller than *L. marinus*, which has pink legs. Non-breeding adult has head less heavily streaked than *L. argentatus*. Juvenile and immature similar to *L. argentatus*, but somewhat darker and more contrastingly patterned. Races differ mainly in size, proportions, and degree of darkness of upperparts: nominate *fuscus* darkest (black), *graellsii* dark neutral grey, *heuglini* variable; S and W races have much heavier head streaking in non-adult plumages. Nominate *fuscus* x *heuglini* hybrids may resemble the lighter *graellsii* or *intermedius*. Rare hybrids with *L. argentatus* have intermediate dark grey mantle, yellow-red orbital ring, and pink legs tinged with yellow.

Habitat. Coastal and inland waters, estuaries, harbours, tropical lagoons, rubbish dumps, fields; breeds mainly on sandy, rocky or grassy sea coasts, rocky islands, islands of lakes and rivers, buildings, moorland, sea cliffs (*heuglini*), but tends to avoid cliffs favoured by *L. argentatus*.

Food and Feeding. Small fish, aquatic invertebrates, nestlings and eggs of birds, carrion, offal, rodents and berries. Baltic herring (*Clupea harengus*) important in diet. In Mediterranean, prefers trawler discards, but during trawling moratorium fed at rubbish dumps, olive groves and rice fields. With increasing competition from *L. argentatus* since 1960's, proportion of marine invertebrates in diet has increased; also more of fish are freshwater species. In one study, took smaller pieces of offal than congeners. Little or no cannibalism. Methods include contact-dipping and surface-plunging; nominate race tends to avoid sites frequented by *L. marinus*, *L. argentatus* and *L. canus*, and forages in deeper water, mainly by plunge-diving. In intertidal zone, more likely to peck at visible food items than to rummage in seaweed or under stones.



Breeding. Arrives at colony in Mar, lays mostly from May (late Apr) to mid-Jun. Colonies usually small in Russia, but large in Britain. Sites include grassy shores, dunes, clifftops, ledges of cliffs or buildings, rooftops; usually well vegetated, nest-sites with denser vegetation than *L. argentatus* in same colony; sometimes under pine trees. Nest of dry stalks, grass, lichens and feathers. 2-3 eggs; eggs and clutch size smaller in years when food scarce; chicks from larger eggs have greater survival; incubation 24-28 days; chick similar to that of *L. argentatus*; fledging c. 30-40 days. In Finland, chick mortality up to 70%, apparently due to (unidentified) disease. First breeding at 4 years. Recorded longevity of 26 years.

Movements. Migratory in most of range. Shows leapfrog migration, with N populations moving farther to winter in tropics, some covering 7500 km to equatorial Africa; many winter in Mediterranean, Red Sea and Persian Gulf, S to Africa. N European breeders move to W & E Africa and Arabia, some wintering on Black and Caspian Seas. Birds from W Europe and W Scandinavia move SW, some move SE, though numbers wintering in breeding area have increased; British birds winter mainly off Iberia and Morocco, a few reaching Senegal coast. Siberian race *heuglini* winters from Middle East and Red Sea E to Pakistan and India, with some reaching the coast of E Africa. Species is now regular though rare in E North America, also wandering accidentally to Pacific coast.

Status and Conservation. Not globally threatened. Total population probably 250,000-300,000 pairs. At least 175,000 pairs in W Palearctic, including 88,700 in British Is. Has increased greatly since 1940's. May be invading North America, where first recorded in 1940's, reaching Hudson Bay in 1969, Florida and Colorado in 1970's, and California in 1978; increasing numbers recorded from Massachusetts to New Jersey, where species now regular but rare. In Netherlands is competing favourably with *L. argentatus*, and has experienced relatively greater growth in numbers. Some colonies of nominate *fuscus*, however, seriously affected by *L. argentatus* predation. Populations in Shetland, Norway and Finland have declined significantly owing to decreasing food availability caused by change in fishing practices, and to competition with *L. argentatus* and *L. marinus*, perhaps abetted by contaminants and by exploitation on W African wintering grounds.

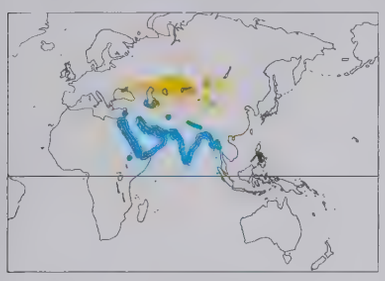
PLATE 52

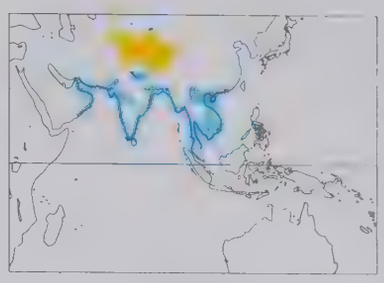


27. Great Black-headed Gull

Larus ichthyaetus

French: Goéland ichthyaète **German**: Fischmöwe **Spanish**: Gavión Cabecinegro

Taxonomy. *Larus Ichthyaetus* Pallas, 1773, Caspian Sea.
Despite large size, behavioural repertoire typical of hooded gulls, although behaviour considered distinctive by some. Possibly a link between the hooded and the white-headed gulls. Monotypic.
Distribution. Breeds in a few very small, scattered localities from Black Sea (Crimea) E to L Balkhash and spottily to NW Mongolia; possibly also N China (Gansu, Qinghai) and Tibet. Winters on coasts of E Mediterranean, Red Sea, S Caspian Sea and N Indian Ocean E to Myanmar; SC Ethiopia.



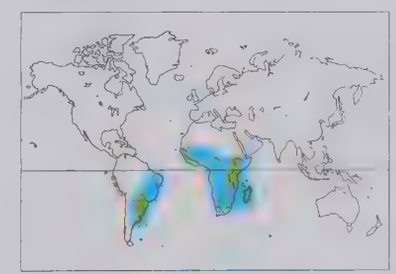
Descriptive notes. 60-72 cm; 900-2000 g; wingspan 155-170 cm. One of the largest gulls, averaging nearly as large as *L. marinus*, sometimes larger; typical hooded appearance, black from face and throat to nape, with conspicuous white eye-crescents; mantle pearl grey; upperwing-coverts very pale grey; flight-feathers mostly white, primaries with conspicuous black subterminal marks and white tips; bill large, orange-yellow, becoming reddish distally, with subterminal black band and yellow tip; legs greenish yellow, with orange webs; iris brown, with thin red orbital ring. Non-breeding adult has white head with dusky area around eye, over ear-coverts and hindcrown. Immature similar to non-breeding adult, but with dark brown flight-feathers and black tail band; bill yellowish with dark subterminal band. Juvenile dark brown above, with prominent pale fringes, very pale below; bill greyish, with diffuse black tip.
Habitat. Coasts and major rivers, harbours, fish ponds, rubbish dumps; breeds on barren islands in fresh and saline lakes and inland seas in generally arid areas, preferring saline soils.
Food and Feeding. Chiefly fish (particularly dead fish) and crustaceans, as well as insects, small mammals, birds, eggs and reptiles. In Volga Delta 88% of diet was fish, including bream (*Abramis brama*) and carp (*Cyprinus carpio*) up to 500 g; also insects and ground squirrels. On Kitai I, rodents (mainly *Spermophilus pygmaeus*) comprised 78% of diet. In cooler weather eats seeds. Frequently piratical on a variety of species. Follows fishing boats; takes fish offal in harbours; one of most solitary gulls. Often flies long distances from colonies to feed aerially on swarming insects.
Breeding. Returns to colonies in early Mar; lays from early Apr. Distinctive courtship displays include raising back feathers, and a howling long call. Colonies of 70-3000 pairs, rarely fewer than 10 pairs; sometimes near but not among *L. argentatus*; single pairs always nest with other gull species, not solitarily. In largest colonies tends to form subgroups of up to 200 nests; small aggregations often linear, parallel to shoreline. Colonies often dense, with nest rims 40 cm apart, especially in centre of colony; at periphery 1-4·5 m apart. Use of breeding areas dependent on fluctuating water levels. Nest of dried aquatic plants and feathers, often on bare rock substrate, sometimes among reeds or other vegetation, or vegetated sand dunes. Very little aggression between neighbours, although gakkering sometimes observed. Normally 2 eggs (1-3); incubation c. 25 days, female sitting for longer spells than male; chick creamy buff or silvery white; recognized by parents by 5th day; may leave territory after c. 5 days; chicks form dense crèche at 7+ days when parents absent or colony disturbed. First breeding usually not until 4 or 5 years.
Movements. Generally migratory, but few details. Migration recorded through NW & C China (Xinjiang, Sichuan). Locally fairly common migrant and winter visitor in Nepal. Recently found to migrate through Red Sea to islands and Ethiopian Rift Valley. Some movement W to Middle East and E Mediterranean (Israel), where apparently much scarcer now than 50 years ago. Immatures may remain in wintering range. Winters mainly on S Caspian Sea, with smaller numbers in Israel (rare), Ethiopia (32-111 birds in mid-1970's), Persian Gulf, S Iran, Pakistan, India and Myanmar. Occasional inland on large lakes and rivers, e.g. c. 100 at Hamun-i-Puzak, SW Afghanistan. Increasingly recorded in Europe, mostly inland; single report from E Atlantic, in Canary Is (Mar 1995).
Status and Conservation. Not globally threatened. Total population unknown, but c. 25,000 pairs in former USSR. Numerous on and N of Caspian Sea, with smaller numbers in Kazakhstan. Bred in Azerbaijan until early or middle 20th century. Apparently stable, but in some colonies expanding populations of *L. cachinnans* cause increased predation. Agricultural benefits from its destruction of insects and rodents considered to outweigh depredation on commercial fish, but still persecuted in some regions. Eggs and young sometimes taken by mammals, e.g. wild boar (*Sus scrofa*), and colonies subject to flooding following storms.
Bibliography. Ali & Ripley (1982), Androsenko (1981), Ash & Ashford (1977), Barthel (1994), Borodulina (1960), Brazil (1991), Britton, P.L. (1980), Cramp & Simmons (1983), Delgushin (1962), Dementiev & Gladkov (1951b), Dowsett & Forbes-Watson (1993), Étchécopar & Hüe (1978), Flint *et al.* (1984), Gladkov (1949), Goodman *et al.* (1989), Ilicev & Zubakin (1988), Knystautas (1993), Kostin & Panov (1982), Lekagul & Round (1991), Mackworth-Praed & Grant (1957), Mierauskas & Buzun (1991), Morris, P. (1971), Samorodov, Y.A. & Ryabov (1969, 1971a, 1971b), Shirihai (1996), Smythies (1986), Urban *et al.* (1986), Vinicombe & Hopkin (1993), Zubakin (1975b, 1976, 1982b).

28. Brown-headed Gull

Larus brunnicephalus

French: Mouette du Tibet **German**: Braunkopfmöwe **Spanish**: Gaviota Centroasiática
Other common names: Indian Black-headed Gull

Taxonomy. *Larus brunnicephalus* Jerdon, 1840, west coast of Indian Peninsula.
Sometimes treated as race of *L. ridibundus*, the Pamir population showing intermediate characteristics. Monotypic.
Distribution. Mountains of SC Asia, between 3000 m and at least 4500 m: Turkestan and W Xinjiang E to SE Gansu, and S to Pamirs (L Kara-Kul), Ladakh and Tibet. Winters on coasts of India, N Sri Lanka and SE Asia, sparingly W to Arabian Peninsula.



Descriptive notes. 41-45 cm; 450-714 g. Hood pale brown, becoming blackish at nape, forming an indistinct collar reminiscent of *L. cirrocephalus*; narrow white eye-crescents towards rear; mantle, back and inner part of wing grey, outer wing-coverts white; primaries white at base, broadly black distally, with white windows on outer 2; bill bright red, with dusky tip; legs bright to dark red; iris pale yellow or greyish, with narrow red orbital ring. Distinguished by wingtip pattern, recalling that of *L. delawarensis*, very different from *L. ridibundus* and *L. maculipennis*, which have largely white outer primaries. Non-breeding adult has pale grey head with grey-brown marks around eye, on ear-coverts, and often across crown; in winter crown becomes pale grey, cheeks and throat white. Immature resembles young *L. ridibundus*, but with sooty brown primaries that are white at the base; bill yellowish, with dusky tip; legs orange.
Habitat. Breeds on islands in large, cold high altitude lakes of varying salinity, or in adjacent marshes; frequents coasts and rivers outside breeding season.
Food and Feeding. Fish, shrimps, offal; also insects, grubs, slugs, earthworms, sewage, potatoes, rodents and plant shoots; occasionally winged termites. Fish, where present, form main diet. On L Kara-Kul, where there are few fish, feeds mainly on invertebrates, particularly adult caddisflies (*Astratus alaicus*) and amphipods. In winter, associates with fishing boats and consumes refuse. Often feeds in shallow water, by immersing head and neck. Catches termites by aerial hawking.
Breeding. Returns to colonies in May; lays from end of May, mainly in early Jun, even when lakes still frozen. Colonies of c. 50 pairs, but reports of several thousand pairs (Tibet); often near Common Terns (*Sterna hirundo*). Nests usually close together, made of masses of plant stems; large, bulky nests built in marshes, smaller nests on land. Usually 3 eggs (1-4, mean 2·4 in Pamirs); incubation and fledging periods unknown (former possibly c. 24 days); chick very pale grey, spotted dark above; mean hatching weight c. 33 g; brooded for most of time up to c. 10th day, only at night until 14th. Even older young may perish in heavy overnight frosts.
Movements. Migrates over mountains to coasts of S Asia; fairly common in Nepal, where some remain to winter. Known to migrate through Hebei, Shanxi and Inner Mongolia also to India, Gulf of Thailand and SE Asia, where often common close inshore and inland. Abundant in winter on Sambhar L (Rajasthan). Less numerous on large rivers.
Status and Conservation. Not globally threatened. Status insufficiently known, but species probably not rare. Virtually nothing known of numbers over most of breeding range, and virtually unstudied except in Pamirs (Tadjikistan), where c. 1000 pairs nest. In winter, large flocks of several hundred birds noted in many parts of India and SE Asia; common in N Sri Lanka.

29. Grey-headed Gull

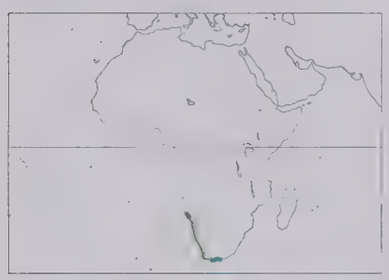
Larus cirrocephalus

French: Mouette à tête grise **German**: Graukopfmöwe **Spanish**: Gaviota Cabecigrís
Other common names: Grey-hooded Gull

Taxonomy. *Larus cirrocephalus* Vieillot, 1818, Brazil.
Morphometric analysis links it with *L. novaehollandiae* and *L. serranus*. Two subspecies recognized.
Subspecies and Distribution.
L. c. cirrocephalus Vieillot, 1818 - coastal Ecuador and Peru; coastal C Brazil to Argentina (S Buenos Aires), and up Paraguay and Paraná basins inland to Santa Fé (Laguna de Melincué).
L. c. poiocephalus Swainson, 1837 - coasts and inland rivers of W Africa; widely scattered localities from Ethiopia to Malawi and S Africa, including Rift Valley lakes (Naivasha, Manyara, Elmenteita, Nakuru, Turkana).

Descriptive notes. 38-43 cm; 250-335 g; wingspan 100-105. Tall, lanky gull with long bill, neck and legs; crown, face and throat grey, bordered with a narrow black line from hindcrown to lower throat; neck, tail and underparts white, a few birds faintly tinged pink below in spring; mantle and wings grey; underwing-coverts dusky; primaries mainly black, with small white windows; bill red, tipped black; legs bright pinkish red; iris yellowish white, with bright red orbital ring. Slightly larger than *L. ridibundus*, and has darker underwing and different wingtip pattern. Non-breeding adult has hint of grey head pattern, without black border; bill duller red, with more extensive black tip. Immature like that of *L. brunnicephalus*, but with darker underwing and narrower dark tail band. Races differ minimally, nominate *cirrocephalus* being c. 2% larger.
Habitat. Tropical and subtropical coasts, offshore islands, and inland lakes and rivers. Breeds on rocky islands, earthen dykes, rarely on coastal dunes; in Argentina mainly in marshes. In Africa, estuaries, harbours, fresh and alkaline lakes; non-breeders also frequent settlements, cattle pens and fishing harbours; remains mainly along shores.
Food and Feeding. Mainly fish and invertebrates, occasionally termites; scavenges broken flamingo eggs and dead fish. In Mauritania preys on eggs of herons and cormorants. Kleptoparasitic on cormorants in Zaire. In winter, scavenges refuse, dead fish and fish scraps. Habits in South America inadequately known. Feeds by plunge-diving; seizes small surface invertebrates while swimming; takes insects by aerial hawking.

On following pages: 30. Hartlaub's Gull (*Larus hartlaubii*); 31. Silver Gull (*Larus novaehollandiae*); 32. Red-billed Gull (*Larus scopulinus*); 33. Black-billed Gull (*Larus bulleri*); 34. Brown-hooded Gull (*Larus maculipennis*); 35. Common Black-headed Gull (*Larus ridibundus*); 36. Slender-billed Gull (*Larus genei*); 37. Bonaparte's Gull (*Larus philadelphia*); 38. Saunders's Gull (*Larus saundersi*); 39. Andean Gull (*Larus serranus*); 40. Mediterranean Gull (*Larus melanocephalus*); 41. Relict Gull (*Larus relictus*); 42. Lava Gull (*Larus fuliginosus*); 43. Laughing Gull (*Larus atricilla*); 44. Franklin's Gull (*Larus pipixcan*); 45. Little Gull (*Larus minutus*).



Breeding. Lays in Apr-May in W Africa (before rainy season), early May in Peru. Colonial; nearest-neighbour distance less than 1 m to a few metres, in Mauritania up to 100 m. Nest on bare ground, in clumps of reeds or papyrus, or on floating vegetation; in Mauritania in tufts of glasswort (*Salicornia*); shallow scrape lined with dry grass and bits of vegetation, to well built cup of rushes and grasses. 3 eggs in South America, 2-3 in Africa (mean 2·4 in E Africa); incubation and fledging periods undocumented; chick buffy yellow, spotted black on head and upperparts, forming irregular linear pattern.
Movements. Many populations are permanent residents or disperse short distances, with many inland breeders moving to coast. Birds from Natal move up to 2000 km N along Atlantic or Indian Ocean coasts. Dispersal apparent along coasts of W Africa and Argentina. In Peru, occurs as far S as Mollendo between Jul and Sept. Vagrants recorded N to Panama, and to Spain and N Red Sea.
Status and Conservation. Not globally threatened. Status inadequately known, but world population reckoned to be under 50,000 pairs. Centre of abundance in equatorial Africa, with several colonies greater than 2000 pairs in Senegal, Kenya and Tanzania; common seasonally at L Chad; abundant breeder (1000's) at Massambwa (L Victoria); c. 200 pairs in S Africa. Suffers serious problems from egging in some areas, e.g. W Africa. Neotropical population uncensused, but few known nesting areas. In E South America probably under 10,000 pairs; rare on Brazilian coast, and very rare in Uruguay; considered fairly abundant in Entre Rios (NE Argentina), but breeding not specified. On Pacific coast has become common only since 1920's, and was not recorded there by earlier expeditions; first discovered nesting W of Andes in 1967, in Peru at Laguna Grande (Ica); only a few known breeding sites, but probably c. 1000 pairs in Peru.

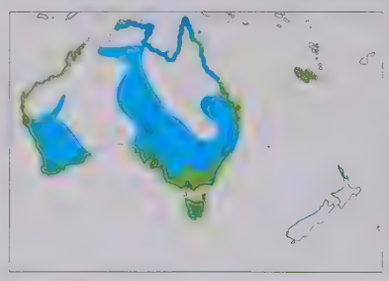
(1989), Winterbottom (1961b), Zoutendyk & Feely (1953), Zuquim (1991).

30. Hartlaub's Gull

Larus hartlaubii

French: Mouette de Hartlaub **German**: Hartlaubmöwe **Spanish**: Gaviota Plateada Surafricana

Taxonomy. *Larus* (*Gavia*) *Hartlaubii* Bruch, 1853, Cape of Good Hope.
Little known and requiring substantial study. Forms superspecies with *L. novaehollandiae* and *L. scopulinus*; often treated as a race of the former, but now usually considered a separate species, closely related also to *L. cirrocephalus* and *L. ridibundus*. Monotypic.
Distribution. Coastal SW Africa, mainly from C Namibia (Swakopmund) to SW Cape Province (Dyer I).



Descriptive notes. 37-39 cm; 235-340 g; wingspan 89-92 cm. White-bodied, with grey mantle; often a suggestion of a faint lavender-grey hood with darker border; outer primaries black, with small white windows; bill and legs deep red; eye brown. "Hooded" birds very like a pale version of *L. cirrocephalus*, but eye is dark, not white. Non-breeding adult fully white-headed. Juvenile has white head and body, no dark ear spot; back and wings brown, marked with pale buff.
Habitat. Coasts, harbours, wet lawns, rubbish dumps and slaughterhouses. Breeds on low, flat islands, including artificial islands and dykes in sewage lagoons and salt-works; sometimes on buildings.
Food and Feeding. Marine invertebrates, small fish, earthworms, insects, offal and refuse. Occasionally feeds on emerging kelp-flies and flying termites, and behind ploughs. Feeds by plunge-diving, swimming, and aerially; also scavenges.
Breeding. Much conflicting information, and laying variously listed as Feb or Apr to Sept, or peaking Apr-Jun; begins breeding in Nov in N, Jan in S; at Swakopmund, breeds throughout year. Frequently nests with Greater Crested Terns (*Thalasseus bergii*), and may be displaced by them. Colonies of 10-1000 pairs, with inter-nest distance usually 1-2 m. Prefers bare or slightly vegetated ground; sometimes roofs. Nest a slight hollow with variable lining material, occasionally 50 cm up on shrubs. Usually 1-3 eggs (1-5, mean 1·8); shell comstitiutes 11·6% of fresh weight, greater than in almost all other gull species; many eggs lost, replacement clutches having lower survival; incubation c. 25 days; incubating gulls responded to human intrusion at distance of 5 m, returning quickly to nest after intrusion; chick buff with black spots, pale on belly; average hatching weight 28 g, by 5th day 68 g; fledging c. 40 days. Productivity often very low. First breeding at 3 years.
Movements. Non-migratory. Disperses to mainland coast in both directions; wanders N on Atlantic coast, and rarely E to Natal.
Status and Conservation. Not globally threatened. Total population estimated at c. 31,000 individuals in 1990, based on 12,000 pairs now breeding at 31 localities; species may be vulnerable. Declining in Namibia, but increasing in Cape Province; 28% of population at Robben I. High rate of breeding failure from both man-induced and natural causes; 60% mortality documented around fledging period, mainly from predation; roof-nesting hazardous, as chicks run off the edge. Main cause of egg mortality was displacement of incubating gulls by *Thalasseus bergii*; displaced gulls usually renest, but replacement clutches average smaller and survival lower than in initial nests. Some advocate that control of *T. bergii* could benefit present species. *L. dominicanus* takes eggs, chicks, and occasionally adults; Sacred Ibises (*Threskiornis aethiopicus*) and Cattle Egrets (*Bubulcus ibis*) eat eggs and chicks. Mongooses (*Herpestes*) are also major predators.

(1977, 1990), Cooper (1976a, 1977b), Cooper & Pringle (1977), Cooper *et al.* (1977), Crawford (1995), Dowsett & Forbes-Watson (1993), Ginn *et al.* (1989), Graham & Brooke (1985), Hofmeyr (1991), Mackworth-Praed & Grant (1962), Maclean (1993), Robertson & Wooller (1981), Ryan (1987), Simon (1977), Sinclair (1977b), Steele (1989, 1992a, 1992b), Tinbergen & Broekhuysen (1954), Underhill & Underhill (1986), Urban *et al.* (1986), Walter, C.B. (1984), Williams, A.J. (1977b, 1989, 1990), Williams *et al.* (1990), Winterbottom (1971), Zoutendyk & Feely (1953).

31. Silver Gull

Larus novaehollandiae

French: Mouette argentée **German**: Silberkopfmöwe **Spanish**: Gaviota Plateada Australiana

Taxonomy. *Larus Novæ-Hollandiæ* Stephens, 1826, New South Wales.
Forms superspecies with *L. hartlaubii* and *L. scopulinus*, and all three sometimes treated as a single species. Morphometric analysis of skeletal characters links prtesent species consistently with *L. maculipennis*, *L. serranus* and *L. cirrocephalus*. Tasmanian birds sometimes separated as race *gunni*, but variation only clinal. Two subspecies recognized.
Subspecies and Distribution.
L. n. forsteri Mathews, 1912 - N Australia; New Caledonia and Loyalty Is.
L. n. novaehollandiae Stephens, 1826 - S Australia and Tasmania.

Descriptive notes. 38-43 cm; 260-350 g; wingspan 91-96 cm. White head, body and tail, blending into grey mantle, back and wings; outer primaries mostly black, with white subterminal spots on outer 3, inners white at bases; bill entirely bright red; legs dull red; iris whitish, with narrow fleshy red orbital ring. Bare-part colours duller in W than in E. Sexes differ in bill depth, male over 11 mm and female under 11 mm. Juvenile has brown markings on head, brown-mottled mantle, scapulars and upperwing-coverts, and a dark brown subterminal band on the tail; bill, iris and orbital ring dark; legs vary from flesh to blackish. Moults into adult plumage at c. 12 months. Race *forsteri* differs in being slightly larger.
Habitat. Both coastal and inland locations, frequenting sandy and rocky shores, parks, beaches and rubbish dumps, as well as inland fields; some birds frequent slaughterhouses and livestock pens. Breeds on small islands and points, mainly with low vegetation, mainly offshore, but also on freshwater and brackish lakes; off South Australia mostly on marine islands, but also on islands in lakes, on breakwaters, and on causeways in salt-pans.
Food and Feeding. Very varied. Refuse, fish, fish offal, marine and terrestrial invertebrates, berries, seeds and insects. Has been observed on water's surface 30 km offshore, eating pelagic amphipods (*Hyperia gaudichaudi*); inland flocks feed similarly on brine-shrimps. Patrols the edge of seabird colonies. In some disturbed colonies, opportunistically takes eggs of conspecifics. Occasionally steals food from terns and pelicans. At Sydney, refuse is an important constituent of diet during breeding season for 85% of adults, while 5-25% feed mainly on natural foods; amount of natural food increased as chicks hatch. Scavenges along shore. Often seen hawking flying ants; kelp-fly larvae and locust swarms attract large flocks. Feeding in ploughed fields is a relatively recent occurrence, but now common. Frequent visitor at picnic sites.
Breeding. Covers all months. Lays from Mar to Nov in W Australia, some pairs raising 2 broods per year; from Jul in S; "winter" breeder in N. Older birds nest earlier, and produce more young. Often chooses same territory and mate in successive years. Colonial, occasionally solitary. May nest close to terneries, particularly of Greater Crested Tern (*Thalasseus bergii*), as does *L. hartlaubii* in Africa. In tropical areas colonies tend to be small (3-25 pairs); up to 3000 pairs in South Australia; colony size limited by immediate food availability. In Capricorn Group in Great Barrier Reef, nests mostly on ground (on sand, low vegetation, rocks), under trees and shrubs, sometimes in bushes up to 2·5 m up; closer than random to trees, with greater vegetation cover, but less grass around nest. Nests vulnerable to flooding. Nest a shallow cup. Usually 3 eggs (1-5); eggs and clutch sizes smaller in drought years; incubation 21-27 days; chicks remain in colony until c. 4 weeks, when led away by parents; parental care ceases at c. 6 weeks. First breeding usually at 4 years, sometimes 3; c. 24% of ringed chicks returned to colony at 2 years, but less than 1% produced young. Reproductive life c. 11 seasons.
Movements. May wander widely outside breeding season. Some populations move short distances, mainly from colony to nearby coastlines. S populations more likely to migrate N; general movement in E Australia is N, but in W Australia is S. Some W movement also takes place along S coast.
Status and Conservation. Not globally threatened. Abundant and increasing, especially in S of range. Over 500,000 pairs at c. 200 colony sites in Australia. Occasionally a pest at airports, and at colonies of other seabird species. Status in New Caledonia unclear.
Bibliography. Beehler *et al.* (1986), Blakers *et al.* (1984), Bregulla (1992), Burger & Gochfeld (1987a), Carrick & Murray (1964), Carrick *et al.* (1957), Coates (1985), Domm & Recher (1973), Gibson, J.D. (1991b, 1992b), Smith, G.C. & Carlile (1992a, 1992b, 1993), Smith, G.C., Carlile & Louwerse (1991), Smith, G.C., Carlile & Tully (1992a, 1992b), Walker (1988), Wheeler & Watson (1963), Wooller & Dunlop (1979, 1981a, 1981b).

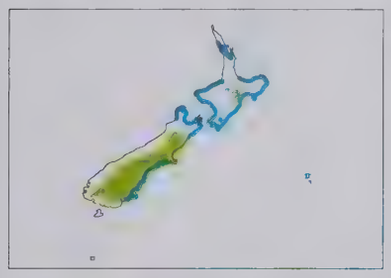
32. Red-billed Gull

Larus scopulinus

French: Mouette scopuline **German**: Rotschnabelmöwe **Spanish**: Gaviota Plateada Neozelandesa

Taxonomy. *Larus scopulinus* J. R. Forster, 1844, Dusky Sound, South Island, New Zealand.
Forms superspecies with *L. hartlaubii* and *L. novaehollandiae*, and usually considered a race of latter. Exceptional mixed pairs with *L. bulleri*, producing fertile hybrids, but the two appear behaviourally isolated. Monotypic.
Distribution. New Zealand, breeding mainly on E coasts of North I and South I, and inland at L Rotorua (North I); also Stewart I, Chathams, Bounties, Snares, Aucklands and Campbell I.

Descriptive notes. 37 cm; 245-360 g; wingspan 91-96 cm. Head, body and tail white; mantle and wing-coverts pale grey; outer primaries black, tipped white, with large white mirrors; inner primaries (6-3) mainly white with narrow black tips, producing conspicuous white wing patch in flight; bill and feet scarlet; iris yellowish white, with narrow red orbital ring. Female slightly smaller and slighter-billed. Differs from *L. novaehollandiae* in slightly smaller size, slightly darker upperparts and relatively deeper bill. Non-breeding adult similar to breeding, but with bill and feet duller red. Immature like adult, but with brown patches on secondaries and buffy tips to feathers on brown back; primaries mostly black; iris, bill and legs dark brown.
Habitat. Coasts, lakes, rubbish dumps, sewage outfalls, fishing piers, wet lawns, and fields. Breeds on rocky beaches, islands, and stacks, rarely on inland lakes.



Food and Feeding. In breeding season, mainly euphausiid krill (*Nyctiphanes australis*) and other planktonic crustaceans, but also earthworms, insects and small fish; at other times diet more varied, including more fish and refuse. Kleptoparasitism on other seabirds and waders common. Feeds behind plough; sometimes eats berries.
Breeding. Most data from 29-year study of Kaikoura colony (NE South I). Begins nesting Jul; prolonged egg-laying (late Sept to Dec), with peak in Oct (mid-Nov on subantarctic islands). Colonies very dense on the main islands; small groups or even solitary on subantarctic islands. Almost all birds, particularly males, return to natal colony; retain mates from year to year; early pairs take central territories. Large number of non-breeders frequent colony. Territory defended for long period; nest building begins 2-3 weeks prior to laying; courtship feeding rare until c. 3 weeks before laying; mounting begins about same time, often following feeding. Normally 2 eggs (1-5); older females lay larger eggs; egg and clutch sizes reduced when less food available; incubation 22-26 days; fledging 28-35 days. Productivity low: c. 33% of adults never fledge young in their lifetime, and only 17% of males and 24% of females recruited young into population. Some birds breed at 2 years, most not until 4-5 years; males breed at younger age than females.
Movements. Leaves breeding areas in mid-Jan. Most adults remain within 380 km of colony, while juveniles disperse further N. Adults ringed at Kaikoura have reached North I (Auckland).
Status and Conservation. Not globally threatened. Total population probably over 500,000 pairs. As with many gulls, this species has increased dramatically through most of 20th century, benefiting from supplementary winter food at fish-processing plants and rubbish dumps. Legislation limiting discharge of offal has been followed by a decline in numbers of present species. Colonization of inland area of L Rotorua (North I) was facilitated by agricultural practices making food available. Eggs are subject to predation by stoats (*Mustela erminea*).
Bibliography. Chambers (1989), Cunningham (1946), Fleming (1946), Gurr (1967), Gurr & Kinsky (1965), Marchant & Higgins (1996), Mills (1969, 1970, 1971, 1973b, 1979, 1989, 1991), Morris (1976), Reid & Reid (1965), Robertson (1985), Stidolph (1947), Tasker & Mills (1981), Williams (1975), Wooller & Dunlop (1981b).

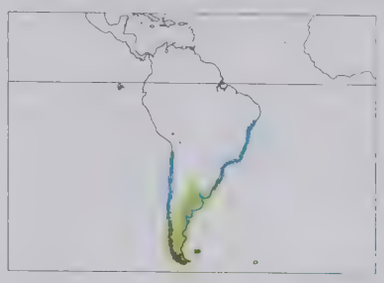
33. **Black-billed Gull**

Larus bulleri

French: Mouette de Buller **German**: Maorimöwe **Spanish**: Gaviota Maorí

Taxonomy. *Larus bulleri* Hutton, 1871, New Zealand.
Rarely hybridizes with *L. scopulinus*, even where breeding alongside (L Rotorua). Morphometric analysis links it with *L. ridibundus* or *L. genei*. Monotypic.
Distribution. New Zealand, on South I and at a few sites on North I (Rotorua, Gisborne, Clive, Porangahau). Winters mainly on S North I and N South I, some straggling to Stewart I and Snares Is.

Descriptive notes. 35-38 cm; 190-270 g; wingspan c. 90 cm. Very pale gull, distinguished by mainly white wingtip with narrow black trailing border, and long, slender black bill; head, body and tail white; mantle and upperwings, including secondaries and inner primaries, very pale grey; outer 2 primaries white, edged black, with subterminal black bar and white tip; decreasing amounts of black on remaining primaries; bill black, with red-orange gape; legs reddish black, with some brick-orange colour on toes; iris white. Non-breeding adult has black eyelids, and blackish feet marked with orange. Immature similar to adult, with buffy tips to feathers of crown, back and upperwing (by 6 months tips worn away); more black on primaries, and brown patches on secondaries; tail may have partial black marks; iris dark brown; bill pinkish, with black tip; legs flesh, with black markings on feet.
Habitat. Coasts, rivers, lakes, parks, wet lawns, sheep pastures, ploughed fields; breeds almost exclusively inland, mainly on rocky islands in fast-flowing braided rivers and along lake shores, rarely attempting to breed at coastal sites.
Food and Feeding. Mainly earthworms, insects, small fish and aquatic invertebrates; sometimes refuse. Gregarious forager; flocks follow plough, and feed on freshly tilled fields, wet grass and sheep pastures. Most feeding sites suitable for only 1 day, so food highly patchy in time and space; birds leaving colony give a contact call that recruits followers, presumably due to benefits of group foraging. Mean feeding distance from colony 4·7 km. Adept at surface-dipping; hawks aerial insects.
Breeding. Courtship begins in Aug, along coast; colonies occupied by mid-Sept; often deserted early in season when food supply poor. Flocks engage in noisy swoop-and-soar displays. Pairs tend to occupy same nest-site in successive years. Synchronous nest building from early Oct; nest is a deep depression of small sticks, lined with grass. Usually 2 eggs (1-3); incubation 20-24 days, by both sexes, eggs never left unattended; in disturbed colonies families abandon nest within 1 day of hatching; remain longer in undisturbed colonies. When disturbed, chicks flock together and run or swim from intruders, often forming dense rafts attended by a few adults; chicks recognize parents' mew calls; fledging c. 26 days. Can breed at 2 years, but usually at 3-4 years.
Movements. After fledging period, adults and young move mainly to coastal habitats, with some movement N; some reach North I.
Status and Conservation. Not globally threatened. Many colonies vulnerable. Total population c. 100,000 pairs. Present species has increased since colonial times, aided by agricultural practices (ploughing) increasing the availability of insects and worms; plays an important role in controlling insect pests. Breeding habitat is limited, and threatened by vegetation overgrowth with exotic lupins (*Lupinus*). Middens reveal that this species was formerly eaten as food by Maori people.
Bibliography. Allen (1984), Beer (1965, 1966), Black (1955), Burger & Gochfeld (1996), Chambers (1989), Cooper (1991), Daniel (1963), Dawson (1958), Drake (1980), Evans (1970b, 1982a, 1982b, 1982c, 1982d, 1983), Gleeson *et al.* (1972), Gurr (1967), Marchant & Higgins (1996), Reid & Reid (1965), Robertson (1985).



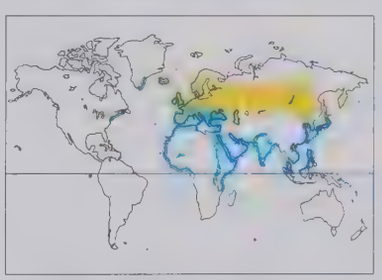
34. **Brown-hooded Gull**

Larus maculipennis

French: Mouette de Patagonie **German**: Patagonienmöwe **Spanish**: Gaviota Cahuil
Other common names: Pink-breasted Gull

Taxonomy. *Larus maculipennis* Lichtenstein, 1823, Montevideo.
Sometimes treated as a race of *L. ridibundus*. Morphometric analysis links it most closely with *L. brunnicephalus* or *L. novaehollandiae*. Monotypic

Distribution. SC Chile and Uruguay S to Tierra del Fuego and Falkland Is; probably also SE Brazil (Rio Grande do Sul). Winters N to N Chile and CE Brazil.



Descriptive notes. 35-37 cm; 290-361 g. Frontal hood chocolate brown to dark brown, darker at rear, forming blackish margin; white crescents behind eye; neck white; underparts white, commonly suffused with pink; back and upperwings grey; outer primaries white, all but outermost primaries tipped black; undersurface of primaries black, with broad white triangle at wingtip (pattern visible at a distance); tail white; bill dark red, blackish distally; legs orange-red; eye brown. Compared with *L. brunnicephalus*, has darker and more uniform head, with less well demarcated black margin. Non-breeding adult (from mid-Feb) has white head with few dark spots behind eye; moults back to breeding plumage in Jun-Jul. Juvenile mottled brown on back, wings and head, with narrow black trailing edge to wing, and narrow black subterminal tail bar; bill dull orange, with black tip; legs brownish. Back and wing-coverts become greyish in 1st winter. 1st-summer birds have a partial dark hood.
Habitat. Sea coasts, rivers, lakes and marshes; in winter also frequents sewage outfalls, slaughterhouses, harbours and fields. Breeds mainly on freshwater or alkaline lakes and *esteros* (marshes) among emergent vegetation (*Scirpus*), but also on rocky peninsulas or high shingle beaches; in Chile among rushes at lakes or rivers close to the sea; in Falklands up to 5 km inland, and in Argentina far inland.
Food and Feeding. Largely insectivorous, but in Chile breeding birds feed mainly on small fish; takes offal and carrion when available. Forages over marshes, damp fields or pastures, and agricultural land; frequently feeds behind plough. Occasionally hawks flying insects. In Tierra del Fuego mainly ■ scavenger.
Breeding. Lays Nov-Dec in Chile, from late Oct to early Jan in Argentina, from Dec in Falklands. Sometimes solitary, but usually in colonies of 5-50 nests, occasionally over 500 nests. In Argentina nests with White-faced Ibis (*Plegadis chihi*) and grebes; in Falklands with South American Terns (*Sterna hirundinacea*) and *Leucophaeus scoresbii*. Nests close together, particularly where plant stems reduce visibility of neighbours. Usurps grebe nest, or may assemble floating nest platform; on dry ground builds bulky grass nest, with cup 25 cm across. Usually 2-3 eggs (1-4; mean 2·6); mobs various intruders, including shorebirds and caracaras; incubation and fledging periods not documented. Chicks remain on nest platform if not disturbed. Solitary breeders sometimes more successful than colonial birds, suffering lower predation by grebes and caracaras. First breeding at 3 years.
Movements. Relatively sedentary, dispersing to large rivers and coastal areas after breeding.
Status and Conservation. Not globally threatened. Status poorly known. Total population probably 50,000-100,000 pairs; c. 600 pairs in Falklands. Common in Chile; usually considered common in E Argentina. Breeding status in Tierra del Fuego unclear.
Bibliography. Aravena (1927), Belton (1984), Blake (1977), Burger (1974b), Canevari *et al.* (1991), Clark (1986), Contreras *et al.* (1990), Croxall, McInnes & Prince (1984), Dubs (1992), Escalante (1970c, 1991), Fjeldså & Krabbe (1990), Hellmayr & Conover (1948), Hudson (1920), Johnson (1967), Klimaitis & Moschione (1987), Meyer de Schauensee (1982), Moynihan (1962), Murphy (1936), Naroski (1969), Olrog (1984), de la Peña (1992), Philippi *et al.* (1954), Pinto (1964), Plotnick (1951), Ruschi (1979), Sick (1985c, 1993), Vooren & Chiaradia (1990), Woods (1988), Zotta (1934), Zuquim (1991).

35. **Common Black-headed Gull**

Larus ridibundus

French: Mouette rieuse **German**: Lachmöwe **Spanish**: Gaviota Reidora
Other common names: Black-headed Gull

Taxonomy. *Larus ridibundus* Linnaeus, 1766, England.
Morphometric analyses link it to various other hooded gulls, with no consistent pattern. Some authors recognize possible race *sibiricus* (NE Siberia). Monotypic.
Distribution. S Greenland and Iceland through most of Europe and C Asia to Kamchatka, extreme SE Russia (Ussuriland) and NE China (Heilongjiang); marginal in NE North America. Winters S to W & E Africa, India, Malaysia and Philippines.

Descriptive notes. 37-43 cm; 195-325 g; wingspan 94-110 cm. Frontal hood dark chocolate brown to dusky blackish, with blackish border; white eye-crescents, mainly behind eye; neck white; underparts white, but in some populations (e.g. in Norway) up to 50% of arriving adults have pink bloom on underparts; back, upperwing-coverts, secondaries and inner primaries grey, secondaries with white tips; outer primaries white, edged and tipped black; tail white; bill and legs dark red; eye dark brown. Distinguished from slightly larger but very similar *L. brunnicephalus* by largely white leading edge to wing, lacking black wingtip with white subterminal spots. Differs from slightly smaller but almost identical *L. maculipennis* in having black tips to outermost primaries. Non-breeding adult has white head, but retains dusky spot on ear-coverts and some blackish clouding on nape. Juvenile has extensive rich buff to darker brown markings on upperparts and upperwing-coverts; black terminal band to tail; bare parts duller.
Habitat. Temperate zone to edge of boreal forests of Palearctic; mainly at low altitudes, and generally near calm, shallow water of coastal or inland waters, including rivers and their estuaries. In winter, tends to occur far more in coastal habitats, but also inland at relatively low elevations. Chiefly inland breeder, with much breeding habitat created by rising water levels, and colonies eventually abandoned when water levels fall and leave dry basin; in many places, however, nests on relatively dry sites, e.g. moors, sand dunes and beaches. Overall, most colonies on freshwater lakes and marshes, but invading certain coastal areas (e.g. coasts of Baltic and North Seas) in huge numbers; in Scandinavia, has recently adapted to colonize salt-marshes, settling ponds, clay pits and coastal dunes and offshore islands. In very wet years may nest in low trees. Often found on sewage farms or near canals.
Food and Feeding. Relies heavily on aquatic and terrestrial insects, earthworms and marine invertebrates, and to lesser extent on fish; also variety of grains. In Baltic, 93% of stomachs contained insects, 5% molluscs, and 3% each oligochaetes (May only) and fish. Feeds by swimming and seizing objects from surface, or dipping head under surface; along coast, by walking on mudflats and probing for shrimps and marine worms; sometimes by foot-stirring and foot-paddling. Also follows fishing boats

and ferries that churn up food items, and may feed at night. Rarely takes berries and acorns from trees. Occasionally kleptoparasitic on terns and other birds, and takes eggs but not chicks of Sandwich Terns (*Thalasseus sandvicensis*). In non-breeding season, also relies heavily on various artificial food sources provided by man, especially in W Europe.

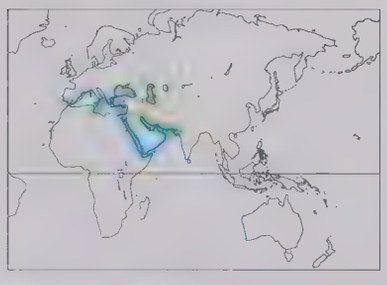
Breeding. Returns to colonies from late Feb to late Mar; lays in late Apr and May. Most colonies 11-100 pairs, a few exceeding 10,000 pairs; inter-nest distances often average 1 m, and large, bulky nests often touch; solitary nesting generally rare, except in Sweden. Shows strong preference for nesting near vegetation, but some colonies deserted because of vegetation overgrowth; very variable substrate, including sand, vegetation, rocks and marshes. 1-3 eggs (mean 2·6-2·78); incubation 22-26 days; chick warm buff, boldly spotted with irregular black blotches on back and wings and smaller, rounder, sparser black spots on head; mean hatching weight declines from 26 g to 23 g during season; adults and chicks recognize each other by 4th day; fledging by 35 days. Young birds likely to return to breed in natal colony; few breed at 2 years. Recorded longevity of 32 years.

Movements. N populations migratory, while lower latitude birds tend to be resident or dispersive. Most birds breeding in Switzerland migrate to W Mediterranean; Scandinavian breeders migrate to Britain and many follow Atlantic coast down to W Africa, but most birds wintering in Britain originate in Baltic republics. Abundant in N Africa especially Egypt in winter; small numbers ascend R Nile; common visitor to Red Sea; uncommon along Rift Valley and E African coast, winter range having extended to tropical Africa fairly recently. Asian birds winter S to India, Malaysia and Philippines; fairly common migrant and winter visitor to Nepal.

Status and Conservation. Not globally threatened. World population close to or perhaps exceeding 2,000,000 pairs, with recent estimates for W Europe of 1,500,000-1,800,000 pairs; as many as c. 300,000 pairs estimated in Sweden alone, and over 200,000 in British Is. Spread and increase impressive 1950-1980, after which slower increase or stability, or even slight decline (e.g. Sweden). Species on increase in Norway and Iceland owing to availability of refuse, but declining in Denmark due to egging and interference by *L. argentatus*. At one site in Netherlands, eggs were collected until 1963 in order to protect colonies of *Thalasseus sandvicensis*; when collecting ceased, population rebounded, increasing from 170 pairs to 6000 pairs in 10 years. Species colonized Ebro Delta, NE Spain, in late 1950's. Range spreading to W: colonized Iceland in about 1910, and Greenland in 1969; numbers have increased in E North America since 1950's, and first bred in E Canada in 1977; now 4 breeding sites known in Canada and New England, but fewer than 20 breeding pairs. In Czech and Slovak colonies, congenital defects numerous, affecting 3-5% of eggs, and particularly common in single-egg clutches; attributed in part to chemical pollutants.

(1956), Weseloh & Mineau (1986), Ytreberg (1956, 1960), Zubakin & Kharitonov (1981).

36. **Slender-billed Gull**



Larus genei

French: Goéland railleur **German**: Dünnschnabelmöwe **Spanish**: Gaviota Picofina

Taxonomy. *Larus Geneï* Brème, 1839, Sardinia.

Nearest relative uncertain: although white-headed, has display repertoire more like that of the hooded gulls, and possibly closest to *L. bulleri*. Formerly listed as *L. gelastes*. Monotypic.

Distribution. Widely scattered, isolated localities from Senegal, Mauritania, S & E Iberia through Mediterranean, Black Sea, Asia Minor and Middle East to E Kazakhstan, Afghanistan, Pakistan and NW India. Winters S to Horn of Africa.

Descriptive notes. 42-44 cm; 220-350 g; wingspan 102-110 cm. Distinctive shape, with long sloping forehead, long, slightly drooping bill, and long legs; head, neck, rump and tail white; back and upperwings grey; conspicuous white leading edge to wing, as outer 5 primaries mainly white, with black tips; underparts white, with rosy bloom on breast and belly in fresh plumage; bill and legs dark red to blackish red; iris yellowish white, with red eye-ring. Non-breeding adult similar, but some show a small dusky auricular spot. Readily distinguished from *L. ridibundus* by more angular profile, with smaller head, longer bill and flat-sloping forehead. Juvenile has buff-grey marks on head, including ear spot and vague partial hood. Immature differs from non-breeding adult in having dark flight-feathers, though primaries with much white, and dusky band on upperwing-coverts; bill bright red to pinkish orange, with small dark tip; legs pale orange or pinkish orange.

Habitat. Almost entirely coastal outside breeding season, feeding in shallow inshore waters and at salt-pans; tends to avoid harbours, but exploits them in Africa. Breeds on coasts of Mediterranean, Black and Caspian Seas and Persian Gulf, and at inland seas and steppe lakes in E Europe to C Asia; utilizes islands, sand spits and beaches, or meadows, grassland, brackish or freshwater marshes of broad river deltas, occasionally in the marine littoral zone.

Food and Feeding. Mainly fish, insects and marine invertebrates, captured alive and scavenged. Fish make up c. 50% of diet; vegetable matter also important. One bird had 3400 bloodworms in its crop. Engages in aerial dipping to surface, plunging from about 1 m, surface-dipping and upending; feeds in intertidal zone, probing in mud with bill; aerial foraging on swarming insects noted. Scavenges far less than most gulls, hence usually does not congregate near villages, but in winter joins other gulls at sewage outfalls.

Breeding. Returns to colonies in late Mar; lays in late Mar to May. Forms colonies of tens to thousands of pairs, often with terns. Preferentially selects open mud, but some birds nest in *Salsola* or *Salicornia*. Nests closely packed; inter-nest distances 20-300 cm (average 42 cm). Some colony-site tenacity, but also shifts colonies between years. 2-3 eggs; eggs much paler than those of most other gulls; incubation 22 days; chick pale grey to pale buff, variably patterned with dark brown or black spots on head and upperparts, with whitish breast and belly; mean hatching weight 28·8 g; adults recognize chicks by 4th day; chicks form crèches, which adults lead towards sea; fledging 30-37 days. First breeding at 2-3 years. Recorded longevity of 23 years 4 months.

Movements. Populations from W Africa, Iberia, Persian Gulf and Pakistan not highly migratory, but generally some dispersal to nearby areas. Birds breeding in C Asia migrate, and mix with the more southerly birds in the Persian Gulf and along Arabian coasts. Most Black Sea birds winter in the Mediterranean, many off Egypt and Tunisia. Regular winter visitor to Red Sea, where some disperse S; may even reach E Africa. Small numbers winter inland, on Black and Caspian Seas.

Status and Conservation. Not globally threatened. Population in W Europe, but recently increasing. World population 75,000-125,000 pairs, with stronghold in Black Sea. Breeding numbers irregular in Spain (10-1000 pairs); also in France, with up to 60 pairs at Camargue, but steady increase to 850 pairs in 1995; 2000 pairs in Italy. Has declined in Romania since 19th century and is now rare. Total European population (excluding former USSR) 2000-3000 pairs. Black Sea population variable and poorly documented; up to 50,000 pairs in some years. On Caspian Sea, currently 450-550 pairs in Azerbaijan. Total of 6000-7000 pairs in Senegal/Mauritania, 3000 pairs in Turkey, and up to c. 5688 nests (1990) in N Egypt. Eggs and chicks preyed upon by *L. cachinnans* and *L. melanocephalus*, particularly when colonies are disturbed by human intruders. Adverse weather not uncommonly causes nests to be flooded; young may perish in cold, wet weather. Contamination by oil can be a problem in Caspian Sea.

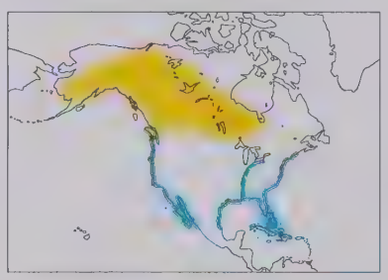
37. **Bonaparte's Gull**



Larus philadelphia

French: Mouette de Bonaparte **German**: Bonapartemöwe **Spanish**: Gaviota de Bonaparte

Taxonomy. *Sterna Philadelphia* Ord, 1815, Philadelphia, Pennsylvania.

Monotypic.

Distribution. W Alaska and S British Columbia E to E Quebec, and possibly N Maine. Winters along Pacific coast S to Mexico (Sinaloa) and on Atlantic coast to Florida and Greater Antilles; in mild winters from Great Lakes to Gulf of Mexico.

Descriptive notes. 28-30 cm; 170-230 g; wingspan 78-84 cm. Hood black, with white eye-crescents; neck and underparts white; back and upperwing, including inner primaries, grey; outer primaries white, tipped black; tail white; bill black; legs orange-red; iris black, with narrow red orbital ring. Non-breeding adult has white head with dark auricular spot, regaining black hood by Apr-May. In all plumages very like *L. ridibundus*, but noticeably smaller, with smaller, black bill. 1st-winter bird very similar, but with darker diagonal bar across upperwing-coverts.

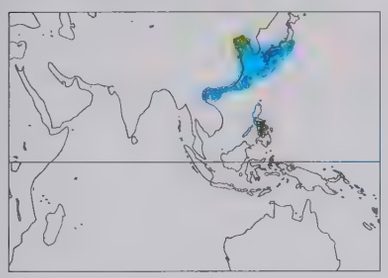
Habitat. Breeds at ponds or muskeg in coastal and inland areas of taiga zone, nesting mainly in spruce (*Picea*) and tamaracks (*Larix*) close to or over water, mostly at low elevation but up to 600 m in Alaska (Denali Park); arrives before snow-melt. Winters on Great Lakes and in coastal estuaries, moving S ahead of freeze-up.

Food and Feeding. Small fish, euphausiids, amphipods, and insects. In British Columbia, euphausiids comprised at least 93% of biomass in spring. On Long I, New York, feeds almost exclusively on small invertebrates, mainly sand-fleas (Amphipoda: Gammaridae). Forages mainly 1-3 m above the water, in flocks of dozens to thousands of birds. Feeds mainly by surface-seizing (51% of attempts) and diving (46%), and by dipping to the surface; occasionally takes swarming insects by aerial hawking. In San Francisco Bay feeds like a phalarope, circling and darting to pick up abundant swarming sand-fleas; also captures them by probing exposed aquatic vegetation. Characteristic feeding pattern is to drift with the surface current, plucking food items from the water, then fly upwind to the front of the flock, land and begin to drift again; birds plunge-diving fly upwind, diving when prey sighted, then veer to the side, fly quickly downwind to the end of the flock, then return upwind over the food source. Concentrates in flocks exceeding 2000 birds over incoming tide. Also feeds at sewage outfalls, particularly at low tide.

Breeding. Arrives in early May; lays late May. Non-colonial, but nests often clumped, with a few pairs in 1 km². Nests in coniferous trees, usually in a muskeg lake or bog pond. Courtship and copulation mainly in trees; copulation often preceded by delivery of nest material. Flat nest c. 25 cm across, c. 3-10 m above ground, built of leaves and twigs bound together by stringy grasses, and lined with grass and moss. Group mobbing occurs where nests are clumped. 3 eggs (1-3); incubation 22-25 days; chick vinaceous cinnamon, spotted with irregular brownish black blotches, with black line through each eye, and unmarked pinkish cinnamon below; may leave nest at a few days old; fledging period not documented. Some breed at 2 years.

Movements. Leaves breeding grounds in Aug in loose flocks, coalescing into larger groups on reaching the coast or the Great Lakes. Alberta breeders migrate to Pacific, those from Saskatchewan to the Mississippi flyway or Great Lakes. E birds migrate SE to R St Lawrence, some moving E to Bay of Fundy, others S across New York to Long I, and others W to L Erie and valley of Mississippi. Winter aggregations of more than 30,000 occur in Bay of Fundy, and more than 100,000 sometimes occur on Niagara R in Nov and L Erie in Dec, prior to freeze-up. Birds move quickly down Maine coast in Sept, and in Oct reach Massachusetts, where they linger until Dec. On Long I numbers peak in mid-Nov, but some remain throughout winter, particularly in mild years. Accidental in Europe and Japan.

Status and Conservation. Not globally threatened. Estimated world population 85,000-175,000 pairs based on averages of Christmas Bird Counts, with 19% migrating to the Pacific, 21% along the Atlantic, and 60% along the Mississippi flyway. Alaskan population estimated to number several 10,000's, and stable.



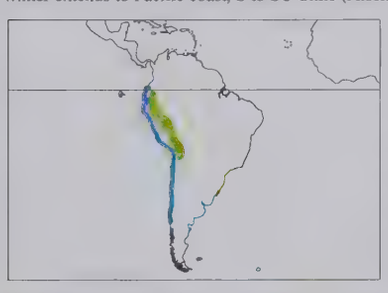
Bibliography. Armstrong (1983), Beardslee (1944), Bohlen (1993), Braune (1987a, 1987b, 1989), Braune & Gaskin (1982, 1987a, 1987b), Brazil (1991), Burger (1967), Burger & Brownstein (1968a), Cramp & Simmons (1983), Drury (1984), Grow (1978), Howell & Webb (1995a), Imai *et al.* (1986), Koonz (1986), Lauro (1980), Lensink (1984), MacLean (1986), Richards (1990), Ridgely & Gwynne (1989), Root (1988), Stedman & Stedman (1989), Stiles & Skutch (1989), Taylor (1993a), Twomey (1934), Vermeer, Szabo & Greisman (1987), Wilbur (1987), Wolf & Gill (1961).

38. Saunders's Gull

Larus saundersi

French: Mouette de Saunders **German**: Saundersmöwe **Spanish**: Gaviota de Saunders
Other common names: Chinese Black-headed Gull

Taxonomy. *Chroicocephalus saundersi* Swinhoe, 1871, Fujian, China.
Quite similar to *Larus maculipennis*; sometimes placed in monotypic subgenus *Saundersia*, based on its compressed bill, its long, slender tarsi, and its incised webs between the long toes. Monotypic.
Distribution. Coastal E China from Liaoning through Hebei and Shandong to Jiangsu. Winters from South Korea and S Japan S to N Vietnam.



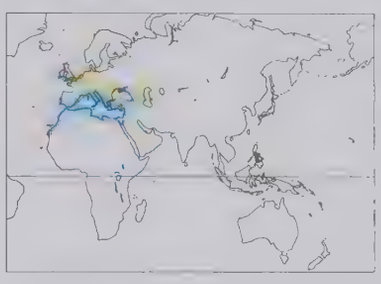
Descriptive notes. 29-32 cm. Head and nape black, with white crescents above and below rear of eye; back and upperwing-coverts blue-grey; outer primaries white, tipped black; inner primaries mainly black, forming diagnostic black patch on underwing beyond "wrist"; secondaries mainly white; bill black; legs and feet reddish; iris dark brown. Non-breeding adult has white head, with grey marks on neck and black spot before and behind eye. Superficially similar to *L. minutus*, but larger, with different upperwing and underwing patterns. Wing pattern similar to that of *L. ridibundus*, but differs in short, heavy, black bill. Resembles *L. philadelphia*, but with disproportionately heavy bill.
Habitat. Mainly along coast, occasionally on bodies of fresh water near coast. Breeds at coastal wetlands, rather than inland lakes as originally reported.
Food and Feeding. Essentially unstudied. Main feeding areas are coastal mudflats, where species presumably feeds on intertidal organisms; also crustaceans and small fish in coastal lagoons.
Breeding. Virtually unstudied. All known colonies are in coastal salt-marshes. Normally 3 eggs (1-6); clutches of 5 and 6 eggs suggest female-female pairing. No published information on other aspects of breeding.
Movements. Poorly known. Birds move S and E off coast of E China, and in winter recorded in South Korea, S Japan, and from E China and Taiwan to Hong Kong, Hainan and N Vietnam. Main wintering areas appear to be S Japan, Hong Kong and N Vietnam. Up to 200 have been recorded at delta of Song koi (Red R) near Hanoi, and up to 90 in Taiwan.
Status and Conservation. ENDANGERED. Total population estimated at below 5000, and probably closer to 3000 individuals, and all 7 known colony sites are either being developed or planned for development for agriculture or aquaculture (particularly for shrimps). The breeding grounds of this poorly known species were not discovered until 1984. It breeds only in four Chinese provinces: Liaoning, with c. 600-700 pairs; Hebei, with c. 25 pairs; Shandong, with c. 200 pairs at 2 colonies; and Jiangsu, with 300-750 pairs at 2 colonies. Oil exploration also destroys the species' salt-marsh habitat and displaces the gulls. Fishermen collect eggs for food. Delayed breeding subjects vulnerable young to late-summer typhoons. Colonies are close to fishing villages, and the frequent human disturbance causes low reproductive success or even desertion. The coastal cities are undergoing industrial development, and this contributes to pollution from coastal sewage and industrial waste. Female-female pairing possibly a consequence of contamination by chemical agents. Extinction very likely by about the year 2010 if breeding habitat is not protected very soon.
Bibliography. Anon. (1988, 1994e), Austin (1948), Austin & Kuroda (1953), Brazil (1991), Brazil & Moores (1993), Collar & Andrew (1988), Collar *et al.* (1994), Étchécopar & Hüe (1978), Ilicev & Zubakin (1988), Melville (1984, 1990), Meyer de Schauensee (1984), Perennou *et al.* (1994), Rose & Scott (1994), Shi Zerong *et al.* (1988), Swinhoe (1871), Takeshita *et al.* (1993), Williams, M.D. (1986), Williams, M.D. *et al.* (1986), Wong (1994), Xu Weishu & Melville (1994).

39. Andean Gull

Larus serranus

French: Mouette des Andes **German**: Andenmöwe **Spanish**: Gaviota Andina

Taxonomy. *Larus serranus* Tschudi, 1844, Jauja Valley, Junín, Peru.
Monotypic.
Distribution. Andean lakes, from N Ecuador to N Chile, W Bolivia and N Argentina (Tucumán). In winter extends to Pacific coast, S to SC Chile (Aisén).



Descriptive notes. 44-48 cm; 478 g. Glossy black hood, with white rear eye-crescents; neck white; back and upperwing grey; unique wing pattern, with broad dark band across middle of black-tipped white primaries, creating a white-black-white-black pattern; from below, distal half of wing is mainly blackish, with large white mirrors on outer 3 primaries; underparts white, sometimes suffused with pink; bill, legs and feet blackish brown, tinged reddish; iris brown. Non-breeding adult lacks black head and has blackish legs, similar in plumage to smaller *L. maculipennis*. 1st-year bird more likely to be confused with *L. cirrocephalus*; has a complex black and white pattern on upper primaries and secondaries, partially dark head, and black subterminal tail band.
Habitat. Lakes, river mouths, marshes and fields; breeds on riverbanks, or on small islets in Altiplano lakes, usually at altitudes of 4000-5300 m, occasionally lower.
Food and Feeding. Earthworms, insects, amphibians, small fish, and sometimes eggs and chicks of various waterbirds. Outside breeding season, takes offal, marine invertebrates and fish.
Breeding. Nests mainly Jul-Aug, but variable, depending on climate. Breeding biology largely unknown. Usually in small colonies, which are remarkably silent; sometimes solitary. Birds leave when intruders approach. Nest among tall grasses and rocks on vegetated islands, or builds floating nest anchored to emergent vegetation, up to 1 m above water. Nests 1-3 m apart (mean 1·3 m), usually at base of rock or vegetation. Usually 2-3 eggs (1-4); eggshell has reduced pores and lower water-vapour conductance than those of gulls breeding at sea-level, but water loss is greater because of increased gaseous diffusion and lower barometric pressure at high altitude; reported to leave eggs unattended for long periods while feeding, but this seems unlikely. Attains adult plumage by 2 years old, but age of first breeding not known.
Movements. Many birds remain on Altiplano lakes and marshes throughout year, but most descend to congregate at river mouths on the Pacific coast; occasionally reaches the Atlantic coastal plain, where may be overlooked.
Status and Conservation. Not globally threatened. Total population unknown, but may be fewer than 50,000 pairs; species probably vulnerable, with no large populations. Centre of abundance in S Peru and N Chile. Most breeding areas are in remote high altitude lakes, but many are increasingly subject to agricultural pressure and human disturbance.
Bibliography. Blake (1977), Burger & Gochfeld (1985a), Butler (1979), Cancvari *et al.* (1991), Carey *et al.* (1987), Fjeldså & Krabbe (1990), Galván (1974), Harris (1981), Hellmayr & Conover (1948), Johnson (1967), Koepcke & Koepcke (1971), Matos (1974), Meyer de Schauensee (1982), Moynihan (1962), Murphy (1936), Olrog (1984), Ortiz & Carrión (1991), Parker *et al.* (1987), de la Peña (1992), Rocha & Peñaranda (1995).

40. Mediterranean Gull

Larus melanocephalus

French: Mouette mélanocéphale **German**: Schwarzkopfmöwe **Spanish**: Gaviota Cabecinegra
Other common names: Mediterranean Black-headed Gull

Taxonomy. *Larus melanocephalus* Temminck, 1820, coasts of the Adriatic Sea.
Formerly often considered to include *L. relictus*. Monotypic.
Distribution. Mainly on Black Sea coasts of Ukraine, with recent spread to N Caucasian Plains and Azerbaijan (Baku archipelago); also at scattered localities throughout Europe, with large numbers recently in Netherlands, S France (Camargue), Italy, Greece and Turkey; also limited breeding in S England, Belgium, NE Germany, NE Spain and C Europe. Winters in Mediterranean, Black Sea, NW Europe and NW Africa.

Descriptive notes. 36-38 cm; 215-350 g; wingspan 98-105 cm. Head black, with prominent white eye-crescents; neck white; upperparts very pale grey; flight-feathers white, with outer web of outer primary black; tail white; underparts white; bill scarlet, with variable dark subterminal band, often mainly on lower mandible, and often with yellow tip; legs bright red; iris blackish brown, with red orbital ring. Differs from *L. ridibundus* in full black hood covering most of nape; bulkier body, larger head, heavier bill, paler general appearance, lack of black at wingtip, and more buoyant flight. Non-breeding adult very pale, with head white but for distinct dark ear-coverts and dark streaks across nape, looking all white at a distance; bare parts deep red to blackish red. Immature like non-breeding adult, but with variable small black marks at wingtips. Juvenile has streaky cap, pale collar, upperparts mottled brown and buff, strongly patterned upperwing with pale grey greater coverts and inner primaries, and white tail with broad blackish subterminal band; bare parts blackish.
Habitat. Coasts, estuaries, harbours, marshes, inland lakes, fields and grasslands. Breeds on Mediterranean coasts, coastal lagoons, steppe lakes and marshes in open lowland areas, favouring sparse vegetation, but generally avoiding barren sand; sometimes on coastal salt-marshes (NW Europe). Appears able to adapt more readily than many other species to new habitats, both breeding and wintering; in recent years has successfully colonized areas which differ markedly from its original habitats in e.g. climate and vegetation.
Food and Feeding. In breeding season, mainly terrestrial and aquatic insects; also gastropods (Greece), and small numbers of fish, rodents and worms. Flocks descend on agricultural fields when abundant insect pests are detected. Obtains beetle larvae behind plough. May fly up to 80 km from colony to feed on grassland. On Russian steppes, sometimes feeds in large flocks on Orthoptera. In some colonies, preys on chicks of *Larus genei* and of Sandwich Tern (*Thalasseus sandvicensis*); unmated birds within colony reported to eat eggs of breeding pairs. On migration and in winter, when shifts to coasts and harbours, consumes fish, molluscs and offal, occasionally sewage and refuse. Feeds by aerial hawking, surface-plunging, contact-dipping, and picking from water surface while swimming. Walks and runs after prey on ground. Scavenges.
Breeding. Returns to colonies in early Apr, most laying first half of May. Highly synchronous, with egg-laying spanning only 10 days. Colonies usually under 1000 pairs; occasionally single pairs in colonies of other species. Often breeds near, but not among, *Thalasseus sandvicensis*; may intermingle with *L. ridibundus*, with which sometimes hybridizes. Nest on sparsely vegetated sites, or thickets or reedbeds, a shallow depression lined with grass. Nests dense, with nest rims as close as 8 cm; average nearest-neighbour distance 63 cm. Usually 2-3 eggs (1-5); incubation 23-26 days, and hatching relatively synchronous; chick spotted brown, grey and buff on head, with 2-3 broad brown bands on buffish back, and pale greyish to pinkish buff underparts; fledging 35-40 days. Productivity often very low. First breeding at 2-3 years. Recorded longevity of 15 years, but no doubt lives longer.
Movements. Mostly migratory, with main wintering areas in the Mediterranean, mainly in Spain. Some birds remain in Black Sea, mostly around N & E coasts, but most move W to Mediterranean. Small numbers reach extreme N of Red Sea in Gulfs of Suez and Aqaba. Also winters along NW African coasts S to Mauritania, rarely to Senegal and Gambia, and off Iberia. Few in NW Europe, mainly in S British Is and W france. Main migration route is coastal.
Status and Conservation. Not globally threatened. Total population c. 300,000-370,000 pairs, with 99% in former USSR, including 90% in Tendrovsky Bay of Black Sea. Tendrovsky Bay population has increased markedly, from c. 93,500 pairs in 1961 to at least 170,000 in 1977 and 330,000 in 1982. In 1989 range spread E, and species bred for first time on Caspian Sea, in Azerbaijan (28 nests). Has expanded W in past 50 years, but still very few pairs breeding from Britain to Italy. Since nesting in Hungary in 1960's, species has bred at least once in most European countries. Recent increase noted in W Europe, with over 125 pairs in Netherlands in 1990, up to 370 pairs in S France (Camargue) in 1995, and 1218 pairs in N Italy in 1988. Main enemies are *L. cachinnans*, corvids and harriers (*Circus*). Extremely susceptible to disturbance, often returning to nest only after some time; this can result in heavy losses and desertion, with instances of up to 98% of nests in colony failing.

Bibliography. Borodulina (1960), Britton, P.L. (1980), Buzun & Mierauskas (1987), Carrera & Garcia (1986), Cramp & Simmons (1983), Dowsett & Forbes-Watson (1993), Dunn (1994), Fasola (1986), Fasola & Canova (1992), Fasola, Bogliani *et al.* (1989), Fasola, Goutner & Walmsley (1989), Goodman *et al.* (1989), Goutner (1986, 1987), Goutner & Isenmann (1993), Grant & Scott (1967), Hoogendoorn *et al.* (1992), Hüppop (1996), Ilicev & Zubakin (1988), Isenmann (1975b), Jansen & Remeeus (1978), Johnson & Isenmann (1971), de Juana (1986), Klimenko (1950), Knystautas (1993), Mainardi (1988), Mayaud (1954, 1956a), Meininger, Berrevoets *et al.* (1991), Modesto (1943), Olsen (1995), Patrikeev (1995), Paz (1987), Richards (1990), Shirihai (1996), Siokhin (1981), Taverner (1976), Urban *et al.* (1986), Zubakin (1982b)

41. Relict Gull

Larus relictus

French: Mouette relique **German**: Reliktmöwe **Spanish**: Gaviota Relicta
Other common names: Central Asian Gull

Taxonomy. *Larus melanocephalus relictus* Lönnberg, 1931, Inner Mongolia.
Originally described as race of *L. melanocephalus*, known only from 1 specimen; then suspected of being an aberrant *L. brunnicephalus* or a hybrid *L. brunnicephalus* x *L. ichthyaetus*. Since breeding colonies discovered in 1970, almost universally considered a distinct species. Monotypic.
Distribution. L Alakol' in NE Kazakhstan; L Barun-Torey in Chita, S Transbaikalia; Tatsain Tsagaan Nuur, C Mongolia; on edge of Edsin Gol, N Gansu, NC China; and Taolimiao-Alashan Nur in C Ordos Highlands, Inner Mongolia. Winter quarters still essentially unknown: probably in SE Asia (Vietnam) and perhaps also in South Korea.

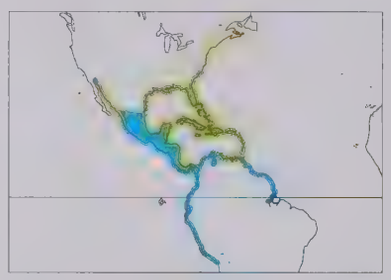
Descriptive notes. 44 cm; 420-665 g. Hood black, grading to pale brown between eye and bill; broad white eyelids, often meeting behind eye; neck, underparts, rump and tail white; mantle, back and upperwing-coverts very pale grey; wingtip pattern distinctive, with outer 5-6 primaries largely white with pale grey base and black subterminal mark, outermost 2-3 having black outer web and primary 9 with broad black patch at tip; stout bill dark red; legs red. Prior to 1970, was probably often misidentified as *L. brunnicephalus*, but is larger, with conspicuous eye-crescents and very different wingtip pattern. Primary pattern similar to that of *L. ichthyaetus*, but latter is considerably bigger. Non-breeding adult loses dark hood, and has dark ear patch and streaking on crown and hindneck. Juvenile has upperparts scaled brown and white, with dark tail band and black outer primaries; bill dark brown, legs dark grey. 1st-winter has head white apart from dark brown mottling on crown and nape; upperwing-coverts extensively marked brown; black subterminal tail band; dark bare parts.
Habitat. Breeds on shores or small islands of arid, usually saline, montane lakes, either on low-lying pebbly or clay rubble islands or spits; usually on islands at least 100 m from shore. Tends to avoid farms or fishing areas.
Food and Feeding. Mainly insects, beetles, small fish and crustaceans; sometimes small birds and mammals (e.g. *Microtus*); occasionally eggs and young of birds. In Inner Mongolia feeds on insects and plant matter, with 90% of food items chironomid larvae. Forages in the surf zone of large lakes and in nearby grassy fields, within 5 km of colony.
Breeding. Highly gregarious. Returns to colonies early Apr to mid-May; lays from early May. Mating reported to occur outside the colony, and also on nest. Frequently changes colony locations. Colonies of 15-2000 pairs, often in discrete subcolonies. Generally beside Gull-billed Terns (*Gelochelidon nilotica*) and Caspian Terns (*Hydroprogne caspia*); sometimes with *L. cachinnans*. Density higher than in any other gull species, with median inter-nest distance of 45 cm. Nest is a scrape surrounded by small stones, usually with small branches and grasses, and feathers. 2-3 eggs (mean 2·4-2·8); incubation 24-26 days; hatching from early Jun (Inner Mongolia); chick pale silvery grey, with fine dark grey spots on back and wings, pure white below; hatching weight 35-43 g; adults attack and often kill intruding chicks of other pairs; young tend to form crèche when alarmed. Chick mortality often high. First breeding at 3 years.
Movements. Migratory, but routes not well documented. Young birds show post-breeding dispersal around colony, before beginning migration in Sept. Has been recorded from over 30 localities, mostly in China; a few records in Hong Kong, Japan and Korea. Part of population migrates through E Gobi; reported from Yellow Sea shores in Apr. Probably winters in SE Asia, e.g. Vietnam, but some may winter in South Korea.
Status and Conservation. Not globally threatened. CITES I. Currently considered near-threatened, but may require reclassification as Vulnerable, due to very low numbers and small range currently known. Total population may be under 2000 pairs. Declining severely in Kazakhstan. In Inner Mongolia, c. 600 pairs nest at the one known colony in Ordos Highlands. Single pair bred at L Balkhash (Kazakhstan) in 1984. Colonies suffer high chick mortality due to adverse weather and predation; *L. cachinnans* may eliminate entire colonies. Extremely sensitive to disturbance in any form. Much research carried out in recent years; much more still needed, especially survey work to establish limits of range, and population size and trends, as well as ecological requirements.
Bibliography. Auzzov (1970, 1971, 1974, 1975, 1977), Auzzov *et al.* (1981), Bakewell *et al.* (1989), Bannikov (1978), Beaman (1994), Borodin *et al.* (1984), Brazil (1991), Collar & Andrew (1988), Delgushin (1962), Dementiev & Gladkov (1951b), Duff *et al.* (1991), Fisher (1985, 1989), Golovushkin (1988), Golovushkin & Ossipova (1989), Grant (1988), He Fenqi *et al.* (1992), Ilicev & Zubakin (1988), Isenmann (1977c), King (1978/79), Kitson (1980), Knystautas (1993), Kovshar (1974), Larionov & Cheltsov-Bebutov (1972), Lönnberg (1931), Melville (1984), Neufeldt & Wunderlich (1980), Ossipova (1987a, 1987b), Perennou *et al.* (1994), Shuker (1993), Stubbe & Bolod (1971), Vaurie (1962), Zhang Yinsun (1991), Zhang & He (1991), Zhang Yinsun, Ding Wenning *et al.* (1992), Zhang Yinsun, Liu Changjiang *et al.* (1991), Zhuravlev (1975), Zubakin (1979a), Zubakin & Flint (1980).

42. Lava Gull

Larus fuliginosus

French: Mouette obscure **German**: Lavamöwe **Spanish**: Gaviota Fuliginosa
Other common names: Dusky Gull

Taxonomy. *Larus fuliginosus* Gould, 1841, Santiago (James) Island, Galapagos.
Not closely related to other dark-bodied gulls, possibly relatively recently derived from *L. atricilla*. Monotypic.
Distribution. Galapagos Is.



Descriptive notes. 51-55 cm. Highly distinctive: head sooty brown to blackish, with white eyelids; body and wings sooty grey, becoming paler grey on belly, with whitish uppertail- and undertail-coverts; tail pale grey, with dark grey centre; bill blackish, sometimes with red towards tip; legs and feet brownish, or purplish black; iris dark, with variable red orbital ring. Juvenile mainly sooty brown, unmarked. 1st-year birds show dark hood, and grey tinge to mantle.
Habitat. Mainly sandy and gravelly beaches on desert islands; also frequents harbours, and associates with boats. Largest numbers seen in Academy Bay, Santa Cruz.
Food and Feeding. Seabird eggs, baby marine iguanas (*Amblyrhynchus cristatus*), small fish, crustaceans, offal and scraps. Mainly a scavenger at tide line, around fishing boats, and at human settlements. Feeds almost exclusively along shore, flying at 3-5 m while scanning for food; rarely settles on sea, but perches on rocks, piers and boats. Associates with sea lions, eating placentae and fish fragments. Hovers over surface of water to snatch floating offal. Pirates crabs from Green-backed (Lava) Herons (*Butorides striatus sundevalli*).
Breeding. Nests throughout year, with peak May-Oct. Solitary nester with large territory, usually on a sandy beach or low outcrop close to water; not on cliffs. First nest found only in 1960; only 6 known by 1970, mostly near saline lagoons. Lays 2 heavily blotched olive eggs in a scrape; incubation 33 days; fledging period uncertain, may be 60 days, but parental care continues subsequently for nearly 3 weeks. Adults very wary at nest, leaving when intruder is still as much as 1 km away.
Movements. Non-migratory, but disperses up to 25 km from nest-site.
Status and Conservation. VULNERABLE. The world's rarest gull. Total population under 400 pairs. Considered globally threatened because of very low numbers, even though its entire habitat is currently protected in the Galapagos National Park system, where it is widely but sparsely distributed; the park is vulnerable to various forms of exploitation and human intrusion, and these pressures are increasing.
Bibliography. Bailey (1961, 1962), Cepeda & Cruz (1994), Collar *et al.* (1994), Coulter (1984), Hailman (1963), Harris (1982), Moynihan (1962), Ortiz & Carrión (1991), Snow & Snow (1969).

43. Laughing Gull

Larus atricilla

French: Mouette atricille **German**: Aztekenmöwe **Spanish**: Gaviota Guanaguanare

Taxonomy. *Larus Atricilla* Linnaeus, 1758, Bahamas.
Considered an excellent "structural ancestor" of all other hooded gulls. Two subspecies recognized.
Subspecies and Distribution.
L. a. megalopterus Bruch, 1855 - SE California to W Mexico (Jalisco), and Nova Scotia to Florida and Texas, locally through E Central America; winters S to S Peru.
L. a. atricilla Linnaeus, 1758 - West Indies to Trinidad and islands off Venezuela; winters S to N Brazil.

Descriptive notes. 39-46 cm; 240-400 g; wingspan 102-107 cm. Hood black, with white eye-crescents; neck, rump, tail and underparts white; mantle, back and upperwings dark slaty grey, with black wingtips, upperwing having a narrow white trailing edge; bill dull red; legs dull red to blackish; iris brown, with red orbital ring. Distinguished from *L. pipixcan* by larger size, heavier bill, more pointed wings, and lack of white in wingtip. Non-breeding adult has white head with light greyish nape band; lacks partial hood of non-breeding *L. pipixcan*, although may, rarely, retain or moult again into a nuptial plumage; bill and legs blackish. Juvenile light brownish above, with feathers edged pale, black on primaries and secondaries, white on throat and belly, and with broad black band on white tail; bare parts blackish. Immature has whiter head, grey back, and dusky breast. Races differ minimally, *megalopterus* having more black in primaries.
Habitat. Strictly coastal. Breeds on vegetated sandy beaches or islands and salt-marshes (Long I to Virginia), and on tops of rocky islands (West Indies). Moves from tidal flats to protected lagoons on rising tide, or during high winds. Visits rubbish dumps, sewage outfalls, beaches, harbours and parks.
Food and Feeding. Aquatic invertebrates and insects (beetles, grasshoppers, ants); also fish, particularly in winter, scraps and refuse. Kleptoparasitic on Brown Pelicans (*Pelecanus occidentalis*), alighting on head of surfacing bird and seizing fish from edge of pouch. In summer (Jun) feeds on superabundant eggs of horseshoe crab (*Limulus polyphemus*) in Delaware Bay, but these have relatively low nutritive value. Scavenges; picks food from surface. Frequently follows tractors; follows fishing boats. Adept at surface-dipping and contact-dipping; hawks flying insects.
Breeding. Lays from mid- to late May in N, in late Apr in Florida. Colonies of dozens to 10,000 pairs; high turnover rate. In West Indies nests under vegetation, but usually near open spaces. Nest of seaweed or grasses on sand or on marsh vegetation. 2-3 eggs (mean 2·6 in Texas); incubation 24-28 days (20 days reported in error); adults remove eggshells, but drop them close to nest; chick hatches weighing 25-35 g; undisturbed chicks remain at nest 1-5 days; chicks recognize parents by day 6; fledging 35-42 days. Nests often subject to flooding; renesting rare unless flooding occurs in early incubation or before.
Movements. Post-breeding dispersal N, followed by movement S. Those breeding in Florida and West Indies largely resident, but N birds migrate as far as South America. In autumn most ringing recoveries are between Cape Cod and North Carolina, but by Feb most birds are in Central and South America. Most ringed birds recovered as adults were within 50 km (but usually N of) natal colony. Winters from Mexico to S Peru, and from North Carolina through Caribbean to Brazil (Amazon). First recorded in Chile in 1990's. Vagrant to Pacific Is, including Hawaii and Galapagos, and regularly to Europe.
Status and Conservation. Not globally threatened. Total population probably c. 400,000 pairs. Abundant and increasing breeder along most of E and S coasts of USA in mid-19th century, but eliminated from much of its breeding range by 1900. With protection from 1913, populations recovered. N population (Nova Scotia to New England), however, which nested mainly on rocky islands, declined again in 1950's owing to competition from *L. argentatus* as latter moved S; marsh-nesting populations from New Jersey and S fared better, and were large enough to tolerate *L. argentatus*. Colonies near airports

considered to constitute a hazard. In Texas, breeding impaired by organophosphates, but not by organochlorine pesticides.

Bibliography. Beer (1969, 1970a, 1970b, 1979), Belant & Dolbeer (1993a, 1993b), Bent (1921), Biaggi (1983), Blake (1977), Blom (1990), Bongiorno (1968, 1970), Bottom (1984), Buckley & Buckley (1984b), Buckley *et al.* (1978), Burger, J. 44. Franklin's Gull

Larus pipixcan

French: Mouette de Franklin **German**: Präriemöwe **Spanish**: Gaviota Pipizcan

Taxonomy. *Larus Pipixcan* Wagler, 1831, Mexico.

Considered closely related to *L. atricilla*, with an almost equally unspecialized display repertoire. Monotypic.

Distribution. Inland North America, from British Columbia to Alberta and from Montana to Minnesota, with scattered populations in N Rocky Mts and Great Basin. Winters mainly off South America, S to Chile.

Descriptive notes. 32-38 cm; 220-335 g; wingspan 87-91 cm. Smallish, somewhat dove-like gull with black hood, bold white crescents above and below eye, and medium-grey mantle and upperwings; secondaries and inner primaries tipped white; outer 5 primaries black subterminally, tipped white, and with white proximal band, producing pale contrast between grey inner wing and black wingtip; tail very pale grey, with white outer feathers; neck and underparts white, latter with pink bloom early in breeding season; bill dull red; legs brick orange to blackish. Non-breeding adult has partial dark hood on rear head, and retains white eye-crescents; bare parts blackish. Distinguished from adults of other gulls by combination of smallish size, dark upperparts, and wingtip pattern. Subadult as adult, but wingtip often with more black and less white. Immature has brownish mantle, all black primaries, a broad greyish brown hood over sides of face and top of head and hindcrown, with a white forehead; unlike *L. atricilla*, black tail band does not reach outer feathers, and underparts white without grey breast band.

Habitat. Coasts, lakes, marshes, fields and rubbish dumps. Breeds exclusively at inland lakes and marshes, over water preferably c. 1 m deep; requires emergent vegetation, although some nests float freely; also nests in dense cat-tails (*Typha*).

Food and Feeding. In breeding season, almost exclusively earthworms or emerging chironomids; also aquatic invertebrates, grasshoppers, and incidentally small rodents and small fish; early arrivals may rely on grain or sunflower seeds before insects become available. Feeds mainly in agricultural fields near colonies. In winter small fish make up an important part of diet, as do fish offal and refuse: feeds along coast, fishing in the surf, and exploits fish factories, sewage outfalls and rubbish dumps. In Peru, feeds on mole crabs (*Eremita analoga*) by walking behind receding waves. Foraging methods include much aerial hawking for insects; follows plough.

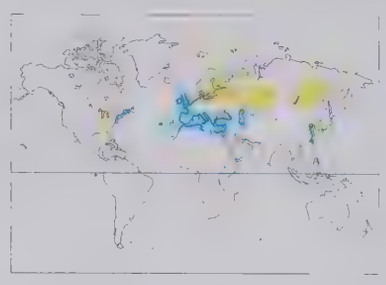
Breeding. Highly synchronous; arrives near colonies in mid-Apr, laying mainly in mid- to late May. Pairing occurs just before arrival. Highly gregarious, with most colonies of 100's, and several greater than 10,000 pairs. Low colony-site tenacity due to fluctuating water conditions. Nest of marsh vegetation; requires daily maintenance, as tends to sink. Normally 3 eggs (1-3); incubation 23-26 days; chicks remain on nest platform unless seriously threatened, then swim into nearby reeds; fledging c. 35 days. First breeding at 3 years.

Movements. Most birds migrate through interior USA to Gulf Coast, then across Mexico to Pacific coast, eventually reaching Peru (Sept) and Chile (Oct), where they remain to early May. Very common visitor to sandy beaches, river mouths and cultivated fields along coast from Ecuador to C Chile, rarely to Tierra del Fuego; occasionally visits Altiplano lakes, e.g. Titicaca; scattered records in Argentina from Córdoba to Chubut. Accidental on Pacific islands, and in Europe and W Africa.

Status and Conservation. Not globally threatened. Total population c. 350,000 pairs in more than 25 colonies. Was rare at the turn of the century, becoming more common after 1915; has recently expanded its range westwards. Each individual colony is vulnerable to vagaries of local water levels, and draining of marshes or drought can eliminate colonies completely. Sensitive to human disturbance early in the breeding cycle, when may completely desert colonies; intrusion during hatching stage can have particularly severe impact. Some mortality from agricultural chemicals, and likely to be vulnerable to effects of El Niño (see Volume 1, page 341) on wintering grounds; protection of breeding habitat is the most important requirement.

Bibliography. Armstrong (1983), Bent (1921), Blake (1977), Blokpoel *et al.* (1992), Brazil (1991), Burger (1971, 1972a, 1972b, 1973a, 1973b, 1974a), Burger & Gochfeld (1984c, 1994b, 1995), Canevari *et al.* (1991), Cikutovic & Guerra (1983), Clapp *et al.* (1982), Collias & Collias (1957), Cramp & Simmons (1983), Dowsett & Forbes-Watson (1993), Drury (1984), DuMont (1940), Easterla & Damman (1977), Érard *et al.* (1984), Fjeldsá & Krabbe (1990), Ginn *et al.* (1989), Guay (1968), Hilty & Brown (1986), Hochbaum & Ball (1978), Holyoak & Thibault (1984), Howell & Webb (1995a), Hughes (1977), Johnson (1967), Kopachena (1987), Kopachena & Evans (1990), Littlefield & Thompson (1981), Maclean (1993), McColl & Burger (1976), Monroe (1968), Murphy (1936), Nicholls (1988), de la Peña (1992), Richards (1990), Ridgely & Gwynne (1989), Rivadeneira (1987), Roberts (1900), Root (1988), Slud (1964), Southern (1980), Stiles & Skutch (1989), Swales & Murphy (1965), Tostain & Dujardin (1989), Tostain *et al.* (1992), Urban *et al.* (1986), Weseloh (1981), Wetmore (1965), White & Kolbe (1985).

45. Little Gull



Larus minutus

French: Mouette pygmée **German**: Zwergmöwe **Spanish**: Gaviota Enana

Taxonomy. *Larus minutus* Pallas, 1776, rivers of Siberia.

Apparently most similar to *Rhodostethia rosea* and *Xema sabini*, although both of these highly divergent from the hooded gulls. Sometimes placed in separate genus *Hydrocoloeus*. Despite disjunct nature of breeding distribution, geographical variation insufficient to warrant subspecific division. Monotypic.

Distribution. N Scandinavia, Baltic republics and W Russia to W Siberia (between R Ural and R Ob'); E Siberia (E from Lena basin and L Baikal); also sporadically in W & C Europe, and casually in North America. Winters mostly S and W of breeding range.

Descriptive notes. 25-30 cm; 88-162 g; wingspan 70-78 cm. Smallest gull, with broad rounded wings, adult with characteristic blackish underwing; flight recalls that of *Chlidonias* terns; head black, with no white eye-crescents; neck, tail and underparts white, breast often with pink flush; mantle, back and upperwings pale grey, wings with white trailing edge; primaries paler grey with white tips, lacking all black; underwing blackish, with white trailing edge; bill dark red to reddish black; legs red. Non-breeding adult has white head with dark cap and ear spot. Immature similar to juvenile, but with grey back. Juvenile blackish on crown, ear-coverts and upperparts, with black outer primaries and black diagonal band across coverts to rear scapulars, forming zig-zag pattern; black tail band; underwing pale; resembles young *Rissa tridactyla*, but smaller, and has weaker flight.

Habitat. Coastal areas, lagoons, sandy beaches, mouths of streams and rivers. Breeds mainly inland, from subarctic to temperate forest and steppe zone, at freshwater lakes, river valleys, marshes and bogs with abundant vegetation; locally at coastal lagoons; nests on sandbanks, in reedbeds and in marsh vegetation.

Food and Feeding. Varied; mostly invertebrates, e.g. dragonflies, beetles and midges. Mainly insectivorous when breeding and on migration; presumably eats mainly small fish and invertebrates in winter. In Baltic, all stomachs contained insects, while only 4% contained fish. Feeds by walking, and swimming; hovers in air and foot-patters on surface. Also feeds tern-like by surface-dipping, flying into wind and dropping to seize insects from surface of water. Occasionally plunge-dives.

Breeding. Lays from late Jun. Older adults return to colony already paired. Readily colonizes new wetlands and abandons old sites. Breeds in small colonies or subcolonies, or as scattered individuals; occasionally up to 1000 pairs. Often nests with other species. Inter-nest distances c. 1-1·5 m. Nest a shallow depression with added grass or reeds, sited on ground in wet vegetation on or adjacent to water, or floating at edge of emergent vegetation (e.g. Ontario); in marshes, incubating adults often obscured by vegetation. Usually 2-3 eggs (1-3); incubation 23-25 days; chick grey-buff, spotted black on crown and back, unmarked whitish below; mean hatching weight 15·1 (Moscow); fledging 21-24 days, with independence a few weeks later. 1st-summer birds often associate with colony, but first breeding not until 2-3 years.

Movements. Poorly documented. After breeding usually gathers in small flocks, occasionally in large groups of thousands, often associating with *L. ridibundus* and Black Terns (*Chlidonias niger*). W population winters along coast, and slightly offshore, from Irish Sea and the Baltic to Mediterranean, Black and Caspian Seas, and off NW Africa (Morocco); large numbers at Nile Delta. Rarely winters inland (e.g. L Turkana, Kenya). Peak migration past Calais (N France) in early Nov. In Netherlands up to 10,000 birds, mainly immatures, present in autumn. W Siberian population migrates through Aral and Caspian Seas to the Mediterranean, where some overlap with more westerly breeders. Movements of easternmost population uncertain; probably migrates to E China, since birds have been recorded in N China in winter. Origin of New World birds uncertain, and may be endogenous breeders or transatlantic migrants; usually seen singly among flocks of other species, particularly *L. philadelphia*, but along Niagara frontier up to 10 noted in Sept and up to 25 in winter.

Status and Conservation. Not globally threatened. Main breeding range in C Asia, hence global population unknown. Marginal and sporadic breeder in most of Europe; up to 21 pairs in Netherlands and 75 pairs in Denmark; under 100 pairs in Sweden and 200 pairs in Finland; 1000-2000 pairs in Latvia. In British Is, substantial increase in passage records occurred in 1970's, apparently involving Baltic breeders. In North America, first bred in Canada in 1962 and in USA in 1975; breeding now documented in Ontario, Quebec, Manitoba, Michigan and Wisconsin.

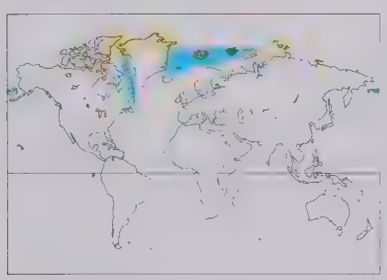
Genus *PAGOPHILA* Kaup, 1829



46. Ivory Gull

Pagophila eburnea

French: Mouette blanche **German**: Elfenbeinmöwe **Spanish**: Gaviota Marfileña

Taxonomy. *Larus Eburneus* Phipps, 1774, Spitsbergen.
Osteologically quite distinct from *Larus*; considered by some intermediate with the skuas (Stercorariidae). Morphometric analysis shows no consistent link with any other species. Has very different display repertoire. Strong rationale for retaining *Pagophila*, though species sometimes placed in *Larus*. Monotypic.

Distribution. Almost circumpolar in Arctic seas and pack ice, breeding from N Canada (Queen Elizabeth Is, N Baffin I) through Greenland, Svalbard, Franz Josef Land, Novaya Zemlya and Severnaya Zemlya to Herald I (New Siberian Is).

Descriptive notes. 44-48 cm; 520-700 g; wingspan 106-118 cm. Very distinctive gull, pure white, with black legs and yellow-tipped blue-grey bill. Immature white, with dusky blackish face and throat, sparse brownish black spots on body and tips of flight-feathers, and narrow dark subterminal tail band. Wing moult apparent in Jun on breeding grounds.

Habitat. Breeds mainly on inaccessible cliffs (W Spitsbergen), on broken icefields and inland cliffs (Ellesmere I), and on low rocks or flat shoreline. Outside breeding season associated with pack ice, favouring areas with 70-90% ice cover near the ice edge.

Food and Feeding. Mainly fish, shrimps, shellfish, algae, carrion, offal and animal faeces. In winter swallows large pieces of frozen food. Since part of its winter range is in continuous darkness, species must feed at night; some stomachs contained only the nocturnal lantern-fish (Myctophidae). Birds wintering at lower latitudes mainly scavenge dead fish. Regularly follows polar bears (*Thalarctos maritimus*), and feeds on scraps from their kills and on bear and seal excrement; eats seal placentae. Associates with human hunters to exploit carcasses. Often reluctant to alight on water, perhaps due to risk of icing. At Spitsbergen, takes marine crustaceans by surface-dipping in flight. Usually tolerant of humans, and even exploits food around camp-sites.

Breeding. Arrives late Mar at Spitsbergen, Apr at Franz Josef Land, and late May in Canadian Arctic and N Greenland; breeds in brief period from late Jun to Aug; most birds do not lay until early Jul. Occasionally does not breed when food conditions are unfavourable. Most colonies of 5-60 pairs, rarely more than 100, with inter-nest distances usually 1-20 m, occasionally over 100 m; rarely solitary. Nest of moss, straw and debris, lined with dry grass and feathers, on bare snow-free rock behind some shelter. 2 eggs; incubation period probably 24-26 days; chick very pale grey above, with indistinct darker grey streaks on wings, white below with pale grey belly patch; fledging at least 4-5 weeks.

Movements. Spends most of year along ice edge, most birds dispersing only as far as edge of pack ice; in summer may even wander N of breeding range. Outside breeding season, most of the breeding population concentrates in Labrador Sea along ice edge of Davis Strait (between Greenland and Baffin I), where largest numbers gather in spring in hooded seal (*Pagophilus groenlandicus*) whelping area; some winter in Bering Sea, also concentrated along ice edge. Odd individuals winter casually S to N Europe and N USA, accidentally as far S as North Carolina; at least one New Jersey record involved a ship-assisted individual.

Status and Conservation. Not globally threatened. Current status essentially unknown. Species may have declined as a result of glacier recession. Documented world population c. 9000 pairs, but true figure must be closer to 25,000 pairs if estimate of up to 35,000 in Davis Strait in Mar 1978 is correct. Status in former USSR largely undocumented. Recent estimate of 1000 pairs on Demashini I in Severnaya Zemlya; also large colony on Tronoy, and c. 250 pairs in NE Greenland; rest of Greenland holds between 100-1000 pairs, and E Canadian Arctic perhaps as many as 1500 pairs. 2000-2500 pairs estimated on Graham Bell I (Franz Josef Land), and up to 1000 on Svalbard. Only 5 Svalbard colonies have been visited twice, and 4 have declined or disappeared; unknown whether this reflects a widespread population decline, or a shift in colony sites.

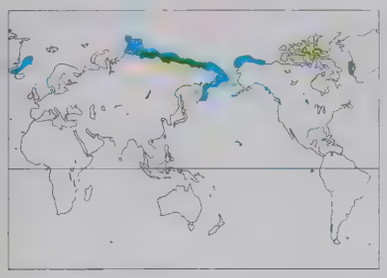
Genus *RHODOSTETHIA* MacGillivray, 1842

47. Ross's Gull



Rhodostethia rosea

French: Mouette rosée **German**: Rosenmöwe **Spanish**: Gaviota Rosada
Other common names: Rosy Gull

Taxonomy. *Larus roseus* MacGillivray, 1824, Melville Peninsula, Canada.

Relationships rather obscure. Resembles *Larus minutus* in size and plumage sequence, but with very different adult plumage. Morphometric analysis suggests it is an early derivative of a primitive larid or of a hooded larid. Monotypic.

Distribution. NE Siberia, from Taymyr Peninsula E to R Kolyma; also locally in Greenland, and irregularly in Canada. Winters mainly in Arctic. Limits of distribution very poorly known for all seasons.

Descriptive notes. 29-32 cm; 120-250 g; wingspan 82-92 cm. Dove-like or tern-like, with a buoyant tern-like flight, and unique combination of wedge-shaped tail (not always apparent), grey underwing and black nuchal collar; in fresh breeding plumage, head, neck, underparts and tail rosy-white; rose colour strongest on breast and belly, more intense than on any other larid, but fades with wear, although still visible on some birds in early Oct; narrow black collar completely encircling head; outer web of outer primary black; white trailing margin to secondaries; bill black; legs bright red to reddish orange; iris dark, with red orbital ring. In flight, characteristic dark grey underwing-coverts with broad white trailing edge to wing. Non-breeding adult lacks black collar and rosy hue, has pale greyish crown, indistinct dusky black flecks around eye, and small black auricular spot. *L. minutus* has more rounded wings, and blacker underwing with narrower white margin. Immature has black outer primaries and broad black diagonal band across inner wing, enclosing broad white triangle on rear upperwing, and broad black tail band.

Habitat. Very few nesting colonies found. Breeds in boggy terrain of the upper taiga and tundra, preferring marshy tundra in river deltas or small ponds with stunted alders (*Alnus*) and willows (*Salix*). Often associates with Arctic Terns (*Sterna paradisaea*) and waders. In non-breeding season, found in open seas and at edge of pack ice.

Food and Feeding. Little information. On breeding grounds chiefly insectivorous; on migration and in winter, mainly marine invertebrates (plankton, crustaceans, molluscs, and even priapulids) and small fish. Reported feeding on wave-washed "scum" on the beach, presumably plankton. Occasionally feeds on walrus (*Odobenus rosmarus*) dung. Forages in small loose flocks or solitarily; may join *Xema sabini* or phalaropes. Often follows ships through ice, capturing organisms on undersurface of disturbed ice. Often feeds by aerial dipping; sometimes by walking, also by surface-dipping. Flocks sometimes gather around dead mammals.

Breeding. Lays in early to mid-Jun. Loose colonies of 2-10 pairs, rarely 18, in tussocks on islands in tundra or taiga pools, often with *Sterna paradisaea*; a nearly unique feature of colonies is their "invisibility". Nest built of dry grass, sedge and moss, often damp, lined with dry grass, sedges and reindeer moss. Nearest-nest distances averaged 43 m, sometimes as much as 100 m, rarely less than 5 m. Social interactions among neighbours very rare; change-overs quiet and unobtrusive. Normally 3 eggs (1-3); incubation 19-22 days; incubating bird flies up at call of incoming mate, which lands and goes to exposed nest; non-incubating mate does not remain on territory; intruders do not elicit alarm calls; chick yellowish to rusty-brown, with dark spots and lines on crown, back and wings, and breast and central belly unmarked whitish; hatching weight 15 g; parental defence aggressive, and also with well developed distraction displays including "rodent-run", "false feeding" and "impeded flight"; adults may lead brood away from colony; at 7 days, chicks left unattended and form groups at water's edge; extremely short fledging period reported to be 3 weeks or less. Fledging rate low, usually less than 33%; hypothermia a frequent cause of chick mortality.

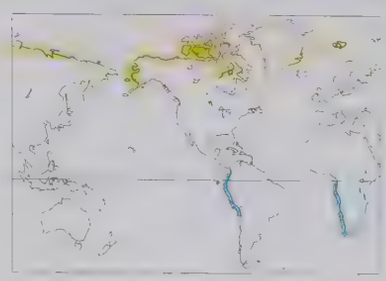
Movements. Post-breeding movement started by late Jul, N to Arctic Ocean, and then migrating E or W along the coast or edge of pack ice; arrives back at breeding grounds in late May, depending on snow and ice conditions. Winter distribution poorly known, but presumably along edge of pack ice. Very rare even in the Bering Sea after winter. Sept-Oct records around Wrangel I and in Chukchi and Beaufort Seas, with birds often flying NE ahead of westerly winds; presumably these birds continue past Barrow, Alaska, where birds first seen in early Aug, with notable movements from late Sept to early Oct when thousands pass NE to feed in Beaufort Sea; many or most return W in Oct-Nov to their unknown wintering grounds. No corresponding spring movement. From Siberia, birds disperse W in Aug-Sept, eventually reaching Franz Josef Land and Spitsbergen. Ocean transect from E Greenland to Franz Josef Land recorded 1000 birds, mainly in groups of 2-16, 90% in adult plumage. Rare visitor to Europe, and accidental in USA in winter.

Status and Conservation. Not globally threatened. Information inadequate to assess true status. Very few breeding localities known, and none regularly monitored. Total population may be as low as 10,000 pairs, but probably closer to 25,000 pairs; even suggested as probably no fewer than 50,000. At least 20,000 (up to 38,000) individuals move past Point Barrow in autumn. Canadian and Greenland populations very small: breeding recorded at 4 sites in N & W Greenland, although permanence of these sites uncertain; all known Canadian colonies have contained fewer than 6 pairs, and indeed entire North American population may not be permanent. Adverse factors on species' numbers include predation on chicks by gulls, skuas and Peregrine Falcons (*Falco peregrinus*). In Canada, nests at Churchill fail frequently owing to human disturbance. Some harvesting of subadults and adults continues at Barrow, and migrants are still shot for food by Alaskan eskimos. Oil development in Beaufort Sea a potential threat.

Bibliography. Andreev & Kondratiev (1981), Armstrong (1983), Bailey (1948), Beaman (1978), Bent (1929), Bledsoe & Sibley (1985), Blomqvist & Elander (1981), Brazil (1991), Brown & Nettleship (1984b), Buturlin (1906), Chartier & Cooke (1980), Cramp & Simmons (1983), Degtyaryev (1991), Dementiev & Gladkov (1951b), Densley (1977a, 1977b, 1979, 1991), Divoky (1976), Divoky *et al.* (1988), Drury (1984), Étchécopar & Hüe (1978), Evans (1984a), Hjort (1980), Hjort *et al.* (1983), Ilicev & Zubakin (1988), Kampp & Kristensen (1980), Knystautas (1993), MacDonald (1979), Meltofte *et al.* (1981), Meeth (1969), Moerbeek (1993), Palmer (1897), Perennou *et al.* (1994), Petersen (1928), Pleske (1928), Richards (1990), Rogacheva (1992), Salomonsen (1950, 1967b), Ticehurst (1933), Williams (1941), Zubakin & Avdanin (1983).

Genus *XEMA* Leach, 1819

48. **Sabine's Gull**



Xema sabini

French: Mouette de Sabine **German**: Schwalbenmöwe **Spanish**: Gaviota de Sabine

Taxonomy. *Larus Sabini* J. Sabine, 1819, Sabine Islands, near Melville Bay, west coast of Greenland. Subspecific variation poorly marked, and species often considered monotypic. Four subspecies currently recognized.

Subspecies and Distribution.

X. s. palaearctica Stegman, 1934 - Spitsbergen E to Taymyr Peninsula and Lena Delta.
X. s. tschuktschorum Portenko, 1939 - Chukchi Peninsula.
X. s. woznesenskii Portenko, 1939 - NE Siberia (Anadyr Gulf) to Alaska.
X. s. sabini (J. Sabine, 1819) - Arctic Canada to W Greenland.
Winters in SE Atlantic off SW Africa, and in E Pacific off NW South America.

Descriptive notes. 27-33 cm; 135-225 g; wingspan 81-87 cm. Highly distinctive, with slightly forked tail, unique upperwing pattern, and delicate, buoyant tern-like flight; hood dark slaty grey, narrowly bordered black at rear; neck, rump and tail white; mantle and back dark grey; inner wing from carpal to scapulars dark grey (as back), outer primaries white-tipped black, leaving contrasting white triangle in between; underparts white, sometimes tinged pink early in breeding season; underwing whitish, outer primaries with black subterminal marks; bill black, with yellow tip; legs blackish grey; iris blackish brown, with bright red orbital ring. By Oct non-breeding adult has white head, with grey hindcrown and nape. Juvenile grey-brown from crown to lower back and on upperwing-coverts (same basic pattern of triangles on wing as in adult); black tail band. Races differ little, becoming darker from E Canada E to Alaska; *woznesenskii* darkest, with extreme slaty upperparts and very restricted white tips to primaries.

Habitat. Arctic tundra, breeding at wetlands with mosses and sedges; on Southampton I, Canada, breeds mainly in narrow band of brackish water habitat just above summer high tide line. Pelagic in winter.

Food and Feeding. Invertebrates and small fish; occasionally small birds, eggs of Arctic Tern (*Sterna paradisaea*) and of conspecifics; carrion. Breeding birds feed mainly on terrestrial prey in marshes; when breeding sites snow-covered at time of arrival, takes Collembola and Arachnida, as well as seeds and plant matter. Non-breeders mainly marine. Swoops low over water and snatches prey from surface; sometimes swims, or feeds on land; feeds plover-like on mud. Rarely hawks insects in the air. In South Africa in winter, adults feed at Cape Town sewage outfall.

Breeding. Returns to colonies in late May to early Jun, when tundra still snow-covered; lays mainly from Jun, depending on latitude and snow cover. Colony size usually 6-15 nests, occasionally up to 60 nests, usually at low density, but nests occasionally only 1 m apart; also nests solitarily. Usually breeds with *Sterna paradisaea*, often as single pairs. Nest of grass, placed on rocky or bare ground with grass or moss cover, near water's edge. Usually 2 eggs (1-3); incubation 23-25 days; chick golden brown above, spotted and streaked, especially on crown and lower back, and brown below with whitish breast and belly; mean hatching weight c. 16·2 g; leaves nest within 3 days, and led by parents to edge of water; adults give distraction display, landing 10-20 m away, and adopting a hunched posture similar to "rodent-run", also injury-feigning.

Movements. Migrates in flocks of few to hundreds of birds, mostly offshore; winters in smaller flocks. Siberian and Alaskan birds migrate through the Bering Sea and Bering Strait, past the Californian coast to W South America, where they frequent Humboldt Current region off Peru. Flocks of dozens regularly seen in Oct off Monterey, California, but most birds probably migrate further offshore. Large numbers of adults from E Canada and Greenland migrate SE through the Atlantic to winter off SW Africa (mostly Namibia and Cape Province), where many adults but very few young are recorded in the Benguela Current region; rarely moves E to Mozambique. Some Canadian birds migrate overland, where recorded from Rocky Mts to Great Lakes, usually solitarily. Autumn storms may drive many birds onto mainland coasts, e.g. in W Europe (over 2000 in W France in autumn 1993, and 850 there in Sept 1995).

Status and Conservation. Not globally threatened. Total population unknown, but probably under 100,000 pairs. Alaskan population reckoned to number several tens of thousands and to be stable. Greenland holds between dozens and a few hundred pairs.

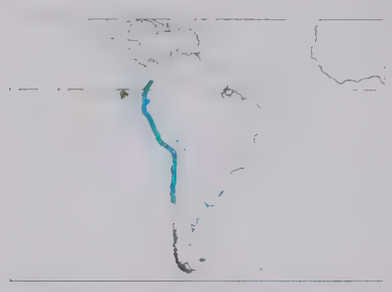
Genus *CREAGRUS* Bonaparte, 1854

49. **Swallow-tailed Gull**

Creagrus furcatus



French: Mouette à queue fourchue **German**: Gabelschwanzmöwe **Spanish**: Gaviota Tijereta

Taxonomy. *Larus furcatus* Néboux, 1846, Monterey, California (error = Galapagos). Morphometric analysis consistently shows this to be a particularly distinctive species. Monotypic.

Distribution. Galapagos, mainly in E half of archipelago; also Malpelo I, off W Colombia.

Descriptive notes. 51-57 cm; 610-780 g. Very distinctive, strikingly patterned gull with deeply forked tail; breeding adult has dark grey head, becoming paler on upper neck and breast; white patch above base of bill; mantle, back and wings grey; rump and tail white; underbody white; bill blackish, with pale tip; legs and feet dull pinkish red; iris dark brown, with broad crimson eye-ring. In flight, shows a broad triangular white patch in centre of wing.

On following page: 50. Black-legged Kittiwake (*Rissa tridactyla*); 51. Red-legged Kittiwake (*Rissa brevirostris*).

Habitat. Virtually endemic to Galapagos Is, where nests on all major and several minor islands, but avoids the colder waters around E Fernandina and W Isabela. Breeds mainly on steep slopes or broken cliffs, often on broad clifftop ledges, but also just above the wave zone; also on gravelly beaches and under vegetation. Many nests readily accessible to humans. Fairly pelagic, and quite often observed feeding 500 km from nearest land.

Food and Feeding. Feeds mostly at night, but also by day; most nocturnal of all gulls, with characteristic large eye. Exploits squid heavily at night, when latter more readily available near surface; also takes clupeid fishes. Regurgitated samples included *Sardinops*, as well as squid (*Symplectoteuthis oualaniensis*). Appears to suffer from periodic food shortages.

Breeding. Breeds throughout year; very asynchronous across Galapagos, but individual subcolonies are synchronized by social interactions. Breeding cycle generally lasts c. 6 months, but 9-10 months for individual pairs. Forms loose colonies with large inter-nest distances; densest colony contained 30 pairs in 200 m²; often solitary. Nests on dirt, bare lava, or gravel, often under rocks and bushes; most nests close to sea. Slight hollow, lined with pebbles, feathers or bones; adults may swallow pebbles and regurgitate them at the nest. Lays 1 egg; incubation 33-35 days, by both sexes, with shift sometimes lasting c. 24 hours; eggshells not removed; chick brooded continuously for first 48 hours, and remains close to nest for several weeks; both parents almost invariably attend nest during daylight; fledging 58-65 days, but young remain near colony and dependent on parents until 90-140 days.

Movements. Adults leave colony after breeding, but return in 4-5 months, often to their previous nest-site; young never return to the same colony. From Galapagos main movement is E. Highly pelagic during non-breeding season, but often seen off South American coast from Ecuador to C Peru, occasionally to C Chile. Accidental in Panama; recorded once in USA (California), presumably a ship-assisted bird.

Status and Conservation. Not globally threatened. Total population c. 10,000-15,000 pairs in more than 50 colonies on all major islands; 50 pairs on Malpelo I, Colombia. Currently protected by Galapagos National Park, but increasing human population and a burgeoning fishery are causes for concern.

Bibliography. Bailey (1961), Blake (1977), Burger & Gochfeld (1993b), Cepeda & Cruz (1994), Coulter (1984), Gifford (1913), Hailman (1964a, 1964b, 1965, 1968a), Harris (1970b, 1982), Hilty & Brown (1986), Lévêque (1964), Moynihan (1962), Murphy (1936), Nelson (1968a, 1968b), de Roy (1984), Snow, B.K. & Snow (1968), Snow, D.W. Genus *RISSA* Stephens, 1826

50. **Black-legged Kittiwake**

Rissa tridactyla

French: Mouette tridactyle **German**: Dreizehenmöwe **Spanish**: Gaviota Tridáctila
Other common names: Kittiwake

Taxonomy. *Larus tridactylus* Linnaeus, 1758, Great Britain.
Morphometric analysis links it with the white-headed gulls. Two subspecies recognized.

Subspecies and Distribution.
R. t. tridactyla (Linnaeus, 1758) - N Atlantic, from NC Canada and NE USA E through Greenland to W & N Europe, and on to N Taymyr Peninsula and Severnaya Zemlya; winters S to Sargasso Sea and W Africa.
R. t. pollicaris Ridgway, 1884 - N Pacific, from NE Siberia, Kamchatka, Sea of Okhotsk and Kuril Is through Bering Sea to Alaska; winters S to East China Sea and NW Mexico.

Descriptive notes. 38-40 cm; 305-512 g; wingspan 91-97 cm. Typical white-headed gull, but with short legs; mantle and upperwing-coverts blue-grey; outer wing slightly paler, with sharply defined, triangular, all black wingtip; bill yellow; legs blackish, very rarely reddish; iris dark brown, with narrow red eye-ring. Distinguished from *R. brevirostris* by paler primary bases contrasting more strongly with grey wing-coverts and black wingtips; also, almost always, by leg colour. Non-breeding adult has dusky grey crown band and nape, usually a darker band across hindcrown, and dark marks around eye. Juvenile and immature have a black zig-zag pattern across the upperwings, a black nuchal band and a black subterminal tail band; resemble young *Larus minutus*, but larger and stockier, with stronger flight. Race *pollicaris* larger, with more extensively black primaries.

Habitat. Arctic and temperate waters. Breeds on coasts as far N as open water occurs, preferring high, steep cliffs with narrow ledges; nests on glacier or snowbank face when it covers traditional cliff sites. In Europe nests also on buildings and piers, and occasionally even on flat rocky or sandy sites, rarely up to 20 km inland. Access to fresh water important. Highly pelagic in non-breeding season, when usually not in sight of land; usually remains on wing, but in severe weather may alight on sea and ride out storms.

Food and Feeding. Mainly marine invertebrates and fish. Outside breeding season also takes planktonic invertebrates, and has recently begun to exploit sewage outfalls and fishing vessels, and to take other offal in estuaries; wintering birds in California ate squid, fish and shrimps. Many species of fish recorded in diet, but sandeels (*Ammodytes*), capelin (*Mallotus villosus*) and herring (*Clupea harengus*) particularly important; also Gadidae (e.g. *Pollachius virens*). Rarely takes bird eggs. More frequently scavenges offal and carcasses. Sometimes feeds on intertidal molluscs and crustaceans, earthworms and small mammals, and on vegetation, e.g. aquatic plants, potatoes and grain. Main fishing methods are surface-dipping with or without foot-pattering, and plunge-diving to c. 1 m below surface; also feeds on surface. Occasionally pirates food from alcids, terns and seals, but is frequently itself a victim of skua piracy. Breeding birds feed mainly within 50 km of colony.

Breeding. Some colonies occupied as early as Jan, and regularly by Feb; lays from mid-May to mid-Jun, depending on latitude; later after cold springs, when many birds do not remain at colony. Usually breeds in huge colonies, many exceeding 10,000 pairs, occasionally over 100,000 pairs, sometimes with other species, especially alcids. Nest-site on narrow cliff ledge, or on ledge or windowsill of building or factory; most courtship, including copulation, takes place on ledge, which is defended most of the year, except in mid-winter. Elaborate nest, incorporating grass and feathers. Usually 2 eggs (1-3); incubation c. 24-28 days; downy chick not cryptic, white with greyish back and wings; remains still on ledge, and begs from 3rd day; guarded continuously for 4 weeks, intermittently thereafter; fledging period variable, c. 5-7 weeks. Poor reproductive success in Newfoundland due to increasing gull predation. Annual adult survival estimated at 95% in Alaska, but only 81% in Britain. First breeding usually at 4 years.

Movements. Post-breeding dispersal from colonies to open ocean, usually well away from coast, and perhaps concentrating at continental shelf or other areas of upwelling. Birds from Greenland remain in Davis Strait until Nov, returning in Mar. Subadults are relatively pelagic. Species is found across entire N Atlantic and N Pacific in winter, and many birds congregate at rich fishing banks off Nova Scotia. Very few ever reach the tropics.

Status and Conservation. Not globally threatened. Has generally increased and expanded its range during 20th century. By far the most abundant gull. Overall world population c. 6,000,000-7,000,000 pairs. Centre of abundance in E Kamchatka, with up to 1,600,000 pairs; also major population in Alaska, where over 1,250,000 pairs estimated in 1977, though only 650,000 pairs in 1990's, with S Alaskan population seriously affected by 1989 Exxon Valdez oil spill (see Volume 1, page 572). About 300,000 in E Canada and New England, and figures ranging from 140,000 to 1,100,000 for Greenland. Old World population exceeds 3,500,000 pairs, including over 500,000 pairs each in British Is, Norway, Iceland and Spitsbergen. In Britain, where was the first species to be protected from slaughter in the 19th century, it has increased and expanded in the 20th century, with annual growth of 2% during period 1969-1979, although populations have now stabilized. Now decreasing in the Faeroes and Iceland but increasing at Bear I, where now more than 200,000 pairs. In S Norway increased by 6-8·5% per year from 1967 to 1975 and by 4-5% per year from 1977 to 1983, but in N Norway only by 1%/year. Few threats, but hunted extensively in Greenland. Gyrfalcons (*Falco rusticolus*) and skuas (*Stercorarius*) prey on adults and young, and Great Skuas (*Catharacta skua*) and *Larus marinus* prey on fledglings.

51. **Red-legged Kittiwake**

Rissa brevirostris

French: Mouette des brumes **German**: Klippenmöwe **Spanish**: Gaviota Piquicorta

Taxonomy. *Larus* (*Rissa*) *brevirostris* Bruch, 1853, north-western North America.
Closely related to and partially sympatric with *R. tridactyla*, but no interbreeding known. Bones found in deposits on Kodiak I. Monotypic.

Distribution. Bering Sea, in Commander Is, Pribilof Is (St Paul I, St George I) and Aleutians (Buldir I, Bogoslof I). Winters widely over N Pacific.

Descriptive notes. 36-38 cm; 340-450 g; wingspan c. 90 cm. Plumage white, apart from dark grey mantle, back and upperwing, grey underwing, and black wingtips; bill yellow; legs and feet bright orange-red to scarlet; iris dark brown, with scarlet orbital ring. Very like *R. tridactyla*, but smaller in all measurements, with shorter, paler bill and steeper forehead; distinguished by darker grey back and upperwing and darker underwing, producing very conspicuous white trailing edge to wing; differs in leg colour, but *R. tridactyla* may rarely have pinkish to reddish legs. Non-breeding adult has dusky grey markings on head and neck. Juvenile and immature have more black on outer primaries, white on inner primaries and secondaries, and black nuchal collar, but lack the black carpal bar and tail band of *R. tridactyla*.

Habitat. Arctic seas. Breeds on vertical sea cliffs on remote islands with other seabirds, including *R. tridactyla*.

Food and Feeding. Fish, squid, and other small marine animals. More than 50% of recorded food items are northern lampfish (*Stenobrachius leucopsarus*); also walleye pollock (*Theragra chalcogramma*, 20%) and various squid and amphipods. Research showed that reliance on squid varied between years from 14% to 82%. Forages both day and night, over deep water along a front of upwellings at the continental shelf. Feeds mainly by pursuit-plunging or dipping. Sometimes forms feeding frenzies over dense schools of fish. Only a single record of kleptoparasitism. Frequent reproductive failures attributed to fluctuating food supplies.

Breeding. Arrives at Pribilof Is in Apr. Apparently, some degree of mate-retention and nest-site fidelity; over 90% of marked birds resighted at Buldir I were within 10 m of marking location. Nest building from May; at Pribilofs, lays from mid-Jun to mid-Jul, with peak hatching in Jul, and peak fledgling departure early to mid-Sept. Nests interspersed with those of *R. tridactyla*, but present species prefers, or is restricted by latter to, narrower ledges averaging 12 cm wide. Nest of mud and vegetation, stamped into a platform, with a shallow cup. Average distance of nearest conspecific neighbour 53 cm. Clutch almost always 1 egg; very sparse data suggest incubation 25-32 days, perhaps averaging slightly longer than in *R. tridactyla*; downy chick has white head, breast and belly, and buffy brown or grey back; hatches with eyes closed and lies still until 2 days old (longer than in most

gulls); brooded constantly until at least 2 weeks old; fledging c. 37 days, but returns to nest-site to be fed for several weeks. Smaller clutch size, longer incubation, less frequent feeding intervals, and slower growth rate are associated with more pelagic feeding habitat compared with *R. tridactyla*.

Movements. Little studied. Birds move S in winter, some keeping just ahead of advancing ice, others dispersing widely over ocean. Many presumably leave Bering Sea; most probably spread over N Pacific E as far as Gulf of Alaska, where recorded in winter; several have been seen S to N Japan. Accidental inland in Alaska and Yukon and Nevada, and as far S as Oregon.

Status and Conservation. VULNERABLE. Endemic to Bering Sea and Aleutians, with only 6-7 currently active breeding sites. Total population formerly c. 120,000-150,000 pairs, but now probably closer to 100,000 pairs. Most breed at St George I in Pribilofs, where recent estimates of c. 57,000 pairs. Commander Is population has apparently increased, from 5000 pairs in 1978 to c. 17,000 pairs in 1992; slight increase at Buldir I, with c. 6600 birds; only 200 at Bogoslof I. In 20th century numbers have declined, and colonies have been abandoned. In Pribilofs, c. 222,000 individuals estimated in 1970's, but reduced by c. 50% since then; attributed mainly to diminishing food supply and increasing fox populations. Clutch size has apparently decreased in past 50 years, as formerly said to be 2-3 eggs. Not all nesting females lay (sometimes only 14% do so), and in some years no eggs at all hatch, or all chicks die. Chicks tolerate human disturbance and overflying aircraft without leaving nests, but foxes and gulls occasionally take chicks from accessible ledges. Some harvesting of adults, chicks and eggs occurs at Pribilofs; enough to prevent population increase at St Paul, but trivial impact estimated at St George. Great increase in commercial trawling may have contributed partially to depletion of food supply. A protective buffer zone around nesting islands is recommended. In Commander Is, nesting areas are protected from access; not formally protected in USA, despite significant decline.

Bibliography. Armstrong (1983), Balch (1980), Beaman (1978), Brazil (1991), Byrd (1978), Byrd & Tobish (1978), Byrd & Williams (1993a), Collar *et al.* (1994), Drury (1984), Firsova (1978), Flint *et al.* (1984), Gabrielson (1933), Hatch *et al.* (1993), Ilicev & Zubakin (1988), Kaufman (1989), Knystautas (1993), Kondratiev (1991), Lensink (1984), Perennou *et al.* (1994), Siegel-Causey & Meehan (1981), Squibb & Hunt (1983), Squibb & Pitts (1982), Storer (1987).

Class AVES

Order CHARADRIIFORMES

Suborder LARI

Family STERNIDAE (TERNS)

- Small to medium-sized slender, graceful seabirds, with long forked tail; most species grey above with black crown, white below.
- 20-56 cm.

- Cosmopolitan.
- Typically marine, coastal or pelagic; some species on inland waters..
- 10 genera, 44 species, 123 taxa.
- 5 species threatened; none extinct since 1600.

Systematics

The terns are a cosmopolitan, highly homogeneous group, closely allied to the gulls (Laridae), and often treated as a subfamily or even a tribe in expanded versions of Laridae. However, there are good reasons for treating the terns as a separate family (see page 572), recognizing the distinctive features which set them apart from all of the gulls. Regardless of the taxonomic level assigned, there is general agreement that the terns are more closely related to the gulls than either is to the skimmers (Rynchopidae) or the skuas (Stercorariidae), although certain authorities argue that some tern species have skimmer-like behavioural attributes, while one morphometric analysis also linked terns and skimmers. On the basis of behaviour, the terns are derived from gull-like ancestors, but they have adopted a more specialized aerial form of feeding and, furthermore, aerial displays play a more prominent role in the courtship of all tern species.

Although terns may have evolved from a primitive larid-like bird as early as the Paleocene, there is no reliable fossil record to provide clues either as to their affiliations with other birds or to the relationships of groups within the tern family. Several species of tern described from the Tertiary were probably misidentified, but a bird from the Miocene of Maryland, USA, originally regarded as a diminutive *Stercorarius* skua, is now considered more tern-like, and may have been a primitive noddy.

Herein, 44 species of terns are recognized in ten genera, although they have been variously classified by other authorities in anything from three to ten genera. A third of the species are "typical" black-capped terns of the genus *Sterna*. They occur throughout the world, but are poorly represented in the tropics. Often referred to as "sea-swallows" because of the long, forked tail, they have grey upperparts, a black cap and whitish underparts, and most have a reddish or black bill and legs; in non-breeding plumage, the soft parts tend to become darker and the forecrown lighter. Several very small *Sterna* terns, once placed in a separate genus *Sternula* and comprising the widespread Little Tern (*Sterna albifrons*) superspecies, are small versions of the typical terns, but with the tail short and notched rather than long and forked; with the exception of the Damara Tern (*Sterna balaenarum*), these "small terns" have a yellow bill with or without a black tip. Three *Sterna* species form the "brown-winged" group: the Sooty Tern (*Sterna fuscata*), the Bridled Tern (*Sterna anaethetus*) and the Grey-backed Tern (*Sterna lunata*) have dark upperparts and a black bill. All three are tropical oceanic species, the first two being pantropical.

The six "crested terns" (*Thalasseus*) are also black-capped, but all are larger than any typical *Sterna* and have elongated crest feathers and most have a bright yellow or orange to orange-red bill. They have characteristic display patterns and breed in very dense colonies, with the nests often arranged in an hexagonal pattern and incubating adults about a body length apart. The chicks of these species tend to form a crèche, particularly when disturbed, a characteristic not found in any other tern except the Sooty Tern. The Chinese Crested Tern (*Thalasseus bernsteini*) is assumed to exhibit the behavioural traits of the genus, although its breeding grounds have never been found. Most recent authors have merged the crested terns into *Sterna*, but they probably form a sufficiently distinct group to warrant generic separation. The Roseate Tern (*Sterna dougallii*) shows a ritualized swaying in its ground displays, which places it between the Common Tern (*Sterna hirundo*) on the one hand and *Thalasseus* on the other.

There are three atypical black-capped terns, each of which is placed in a monotypic genus, although several recent authors differ in their generic treatment of these species. The heavy-billed Gull-billed Tern (*Gelochelidon nilotica*) and the very large and massive-billed Caspian Tern (*Hydroprogne caspia*) both occur on most continents, while the Large-billed Tern (*Phaetusa simplex*), conversely, breeds only on rivers of South America.

The three "marsh terns" (*Chlidonias*) have a short, slightly forked tail and are extensively black or dark grey in breeding plumage. Apart from M. Moynihan (see below), most authors agree that they represent a separate genus. The Black-fronted Tern (*Sterna albostriata*) might be considered to form some sort of a link between *Sterna* and *Chlidonias*, as it is occasionally included in the latter genus.

The noddy group includes 5-7 species in three genera: the typical dark-coloured genus *Anous*, the all white *Gygis*, and the blue and grey *Procelsterna*. The status of closely related forms or species pairs in each of these genera requires further study. The specific status of the Brown Noddy (*Anous stolidus*) is not disputed. The Black Noddy (*Anous minutus*) and the Lesser Noddy (*Anous tenuirostris*), however, with allopatric distributions, are sometimes treated as conspecific, although on present evidence it seems reasonable to treat them as distinct species. A similar case is that of the Blue Noddy (*Procelsterna cerulea*) and the Grey Noddy (*Procelsterna albivitta*) which are herein treated as specifically distinct. In the White Tern (*Gygis alba*),

current research does not favour the separation of the form *microrhyncha*: the two taxa are closely similar in appearance and behaviour, and there is evidence of their interbreeding in the Marquesas.

The monotypic genus *Larosterna* has been recognized by all authors for the Inca Tern (*Larosterna inca*), because of its remarkable plumage pattern and its distinctive breeding behaviour, as this Humboldt Current endemic nests in deep crevices and small caves; a tendency towards this habit is demonstrated by some Roseate and Bridled Terns which nest under boulders.

G. D. Schnell compared different statistical approaches to analysing skeletal and external characters of the terns and their allies, grouping birds on the basis of their similarities. Although there are many inconsistencies, several constant morphological patterns emerge which support the use of separate genera for several species. For example, *Gelochelidon* does not link closely with the typical terns, in many respects showing closer similarity to the crested terns. *Hydroprogne* sometimes links with *Thalasseus*, on the basis of size, but in other analyses it is distantly related to both *Sterna* and *Thalasseus*. *Phaetusa* is most similar to the larger crested terns, but does not consistently link with the smaller-billed ones.

Within the crested terns, Schnell found that the Great Crested Tern (*Thalasseus bergii*) and the Royal Tern (*Thalasseus maximus*) consistently show close affiliations with each other, although not always with the other members of *Thalasseus*, which likewise form a consistently linked group. Interestingly, the "Cayenne" form *eurygnatha* of the Sandwich Tern (*Thalasseus sandvicensis*) emerges as more similar to the Elegant Tern (*Thalasseus elegans*) than to the Sandwich Tern, suggesting that their assumed relationship at the species level warrants closer study.

The Roseate and Black-naped (*Sterna sumatrana*) Terns consistently form a species pair, and Forster's Tern (*Sterna forsteri*) and Trudeau's Tern (*Sterna trudeaui*) another, both of which associations have been suggested on other grounds by many field observers. Black and Lesser Noddies are the most closely similar of any species pair, even when they are not closely linked to Brown Noddy because of size differences. *Procelsterna* (treated by Schnell as a single species) shows morphological similarities to *Chlidonias*, rather than to *Anous*. As expected, *Larosterna* often appeared as a sister group to the remaining terns, although in some analyses it is linked with the noddies on account of its dark plumage.

In his 1959 taxonomic revision of gulls and terns, based on a comparative analysis of behaviour, M. Moynihan noted the uniformity of behaviour among the terns, and, as a consequence, he divided the family into just three genera. He placed the dark and the white noddies in the genus *Anous*, retained *Larosterna* for the Inca Tern, and placed all others, including the marsh terns, in the genus *Sterna*. No other authority has opted for such extensive generic lumping. Moynihan thought that, on behavioural grounds, the Large-billed Tern was closely related to the small terns, while the distinctiveness of the latter led him to conclude that this might justify their generic separation. Other authors differ as to which genera they retain: most recognize *Chlidonias*, *Procelsterna*, *Gygis*, *Larosterna* and *Phaetusa*, but lump all others in *Sterna*; some accept *Gelochelidon* but not *Hydroprogne*, and others the reverse.

More recently, in 1990, C. G. Sibley and B. L. Monroe listed 45 species of terns in seven genera. In addition to *Sterna*, they included *Chlidonias*, *Phaetusa*, *Anous*, *Procelsterna*, *Gygis* and *Larosterna*, while the Gull-billed, Caspian and crested terns were grouped in *Sterna*. The decision as to where exactly the line is drawn ultimately comes down to the extent to which one is a generic lumper or splitter. Herein, contrary to most recent authors, *Gelochelidon*, *Hydroprogne* and *Thalasseus* are retained, as much to emphasize the remarkable uniformity among the remaining typical terns as to stress the distinctiveness of these forms.

Morphological Aspects

Compared with gulls, terns are more specialized in terms of nesting habitat, diet and foraging methods, and their morphology reflects these specializations from a generalized larid ancestor. There is little doubt that the terns have a monophyletic origin. In general, terns forage by plunge-diving for fish or swooping to seize items at the water's surface, and the streamlined body and long, pointed wings and bill are well suited to such foraging methods.

Terns are small to medium-sized birds, ranging from 20 cm to 56 cm in length. There are no sexual differences in plumage patterns, and only slight size dimorphism, with males about 2-5% larger than females; dimorphism in bill size tends to be greater than that in body size. All species have very slender, elongated bodies, unlike the robust rounded shape of gulls, and they have relatively shorter legs, longer and narrower wings and longer bills. Most typical terns have elongated outer tail feathers or streamers, giving them a deeply forked tail, while in almost all other tern species the tail is at least notched. All these structural features produce a style of flight that is swift and graceful, with the distinctive shape giving an almost aircraft-like appearance: the aerial "high-flights" of terns (see Breeding) are among the most spectacular avian phenomena of coastal habitats in spring.

Although a few species are all dark or all white, most terns are pale below and grey above, with a black crown in nuptial plumage. Their white or light grey underparts reduce their con-

Taxonomists have divided the Sternidae into anything from three to nine or ten genera. The noddy genus Procelsterna, *morphologically closer to* Chlidonias *than to* Anous, *is recognized as valid by most authors, but disagreement continues over whether it contains one, two or even three species. The Grey Noddy is still sometimes considered no more than a pale morph of the Blue Noddy* (Procelsterna cerulea).

[*Procelsterna albivitta albivitta*, Lord Howe Island, Australia. Photo: Fred Bruemmer/ DRK]

Despite its initially aberrant appearance, the Inca Tern still possesses the characteristic structural features of the Sternidae, including a rather elongated and slender body, relatively narrow wings, a forked tai short legs and a long bill. Because of its unique plumage pattern and remarkable breeding behaviour, however, it is placed in its own monotypic genus Larosterna. *It is endemic to the Humboldt Current region, where it nests in deep crevices and small caves, quite unlike most typical terns, although one or two* Sterna *species show a certain tendency towards similar nesting sites.*

[*Larosterna inca*, Paracas, Peru. Photo: Günter Ziesler]

spicuousness to underwater prey when they are foraging overhead; this applies to juvenile terns as well, whereas juveniles of most gull species are dark grey or brown below, reflecting less plunge-diving activity. Like gulls, terns have a relatively high percentage of red and orange oil droplets in their eyes, allowing them to see through atmospheric haze above the ocean and to see fish in water to the depths to which they normally plunge. Terns that are dark-bodied engage in less aerial plunge-diving, and more surface- or hover-dipping, than those having a white frontal aspect.

Although short-legged, all terns walk well on the ground, but they are less likely than gulls to engage in running attacks during aggressive encounters. Many terns land on the water to bathe, and a few actually feed from the surface, but for a family with webbed feet, so closely tied to water, swimming is remarkably unusual and uncommon. Nevertheless, chicks in waterside colonies, when disturbed by intruders, often jump into the water and swim skilfully. Sooty Terns, however, do not have water-repellent plumage and quickly become waterlogged if they land on water.

With regard to overall body size, Caspian, Royal, Great Crested and Sandwich Terns are large and weigh over 250 g. Most of the rest are intermediate-sized, weighing about 100-180 g, while the small terns, 80 g or less in weight, include the Fairy (*Sterna nereis*), the Little, Saunders's (*Sterna saundersi*), the Least (*Sterna antillarum*), the Damara, the Yellow-billed (*Sterna superciliaris*) and the Peruvian (*Sterna lorata*) Terns. While there is almost complete overlap in size between males and females of a given species, within pairs the males are often slightly larger than their mates. In some species, such as the Common Tern, males have longer, deeper and wider bills than do females.

The plumage patterns of terns vary as a function of age. The downy chicks of most species are a tan or grey colour with dark speckles or splotches which provide them with camouflage, although in a few species the chicks are uniformly pale grey or black. At fledging, the juvenile plumage is often scaly or speckled above, with a head pattern similar to that of the adult winter plumage. During the summer of their first year, terns normally have a white forehead. Full adult plumage is usually developed by two or three years of age. Melanism has not been reported among terns, and albinism would be difficult to detect in a primarily white family. Leucism has been reported in Black Noddies, and occurs with a frequency of less than 0·01% in juvenile Sooty Terns.

Moult patterns vary among species. The typical and crested terns often begin their body moult during the breeding season, and even incubating birds, particularly those which have relaid, can show white foreheads, while Least and Little Terns begin primary moult during incubation. Those breeding in north temperate environments mostly undergo a partial moult on the wintering grounds prior to migration north. Noddies have protracted moults which extend into the breeding season, as in the Brown Noddy, or they interrupt their moult to breed, as is the case with the White Tern.

Habitat

Terns occur throughout the world and breed on all continents, including Antarctica, where there are colonies of Antarctic Terns (*Sterna vittata*). They exploit a variety of breeding habitats, occupying inland marshes and rivers, coastal marshes and estuaries, sandy or rocky beaches, rocky cliffs, and oceanic islands. Only 11 species regularly breed inland. Historical data from Europe show that there is a "tern zone", located in the lower middle reaches of large rivers, used extensively by nesting Common Terns. Least and Little Terns have populations breeding on inland rivers of North America and Europe respectively, and the closely related Yellow-billed Tern is strictly a riverine species, as is the Large-billed Tern with which it nests, as well as the Black-fronted Tern of New Zealand's South Island. The three marsh terns, Trudeau's Tern and some populations of Forster's Tern nest on inland marshes. A similar number of species, 11, breed on oceanic islands. These are the dark-winged *Sterna*, namely the Sooty, Bridled and Grey-backed Terns, the six species of noddies, and the Antarctic and Kerguelen (*Sterna virgata*) Terns. Some populations of Roseate Terns also nest on oceanic islands. The remaining members of the family breed on rocky and sandy coasts, estuarine and barrier islands, and inshore archipelagos.

During migration most inland breeders move to coastal areas, and outside the breeding season most species of terns re-

The Sooty Tern exhibits all the classic tern features: a slender, streamlined body, long, narrow, pointed wings, and a deeply forked tail with elongated outer feathers, giving an elegant appearance very different from that of the heavier and more robust Laridae. In all aspects of their life terns are far more aerial than the latter, their structure being designed to produce a swift, buoyant and graceful flight in which their shape is quite distinctive. A very common foraging method of terns involves plunge-diving for fish from a height of several metres, a method for which the long, pointed bill and general streamlined shape are ideally suited; the white or pale grey underparts of most tern species reduce their conspicuousness to underwater prey when they are foraging overhead. The Sooty Tern, however, is one of the species that feed mainly by dipping to the water's surface. Oddly, its plumage is not water-repellent, and the bird rapidly becomes waterlogged and unable to fly properly if it settles on water. It therefore spends all of its life in the air apart from periods at the breeding site. Sooty Terns have never been seen to swim or to sleep on water, and are assumed to sleep on the wing. They feed at night, on fish which come to the surface only after dark. The graceful soaring flight of Sooty Terns as they head out to the open ocean to feed is a glorious sight to behold.

[*Sterna fuscata nubilosa*, Glorieuse Islands, western Indian Ocean. Photo: R. Seitre/Bios]

In terns, patterns of daily activity are frequently affected by tidal regimes, but the busiest times tend to be early and late in the day. This is especially true in tropical climes, where birds are likely to spend the hottest hours of the day loafing in flocks at favoured sites. During such periods of rest, individuals may perform different kinds of comfort behaviour; some birds bathe, which they may follow with a session of preening. While one of these River Terns is busying itself in feather-care, the other looks on and indulges in a little wing- and leg-stretching.

[*Sterna aurantia*, Ramnagar, north India. Photo: Tim Loseby]

main along coasts, a few venturing out to the edge of the continental shelf. In the Southern Hemisphere, Arctic Terns (*Sterna paradisaea*), which spend the northern winter in Antarctica, often wander through the pack ice along the edge of that continent. The more highly marine species either stay close to their breeding islands or become entirely pelagic, and the wintering areas of these species, as well as of the Aleutian Tern (*Sterna aleutica*) and several populations of the Roseate Tern, are largely unknown.

Sooty Terns maintain a strictly oceanic existence from the moment they fledge from the nesting colonies until, at about five years of age, they return to land to breed for the first time. One of the great ornithological mysteries is how this species, which lacks water-repellent plumage and soon becomes waterlogged if it lands on the sea, spends these five years; healthy juveniles have never been found on land, apart from a few that return to the nesting areas a year before they actually breed, nor on flotsam, where Bridled Terns often rest. Do these young Sooties remain on the wing for the entire five years between fledging and returning to their natal colonies?

Many terns seek inaccessible nesting places, on islands on barrier beaches, in rivers or on lakes, in marshes, on long extended sand spits, or on remote oceanic islands. On the last of these, several species nest on trees or cliffs. These anti-predator strategies deter most mammalian predators, although rats, cats, foxes and mustelids exact a toll on some inshore islands. Nesting substrates include sand, fine or coarse gravel, shell, dry mud, mats of floating or prostrate terrestrial vegetation, pockets of coral or coral rubble as well as concrete and concrete rubble, and artificial surfaces such as gravel roofs, dykes and other man-made features of the landscape. Some species, including Common and Little Terns, exhibit wide variation in their choice of colony sites and nest-sites, embracing most of the above choices in one part of their range or another. For example, Common Terns will nest on sandy or rocky beaches, in heavily or sparsely vegetated areas, on bare sand, on wrack, mud or bent-over grasses in salt-marshes, on sand or vegetation in freshwater marshes, on rock or rubble beaches, and on man-made structures such as wooden platforms. They may even use several of these different substrates in one local area.

Other species have different habitat preferences in different parts of their geographical range. Sooty Terns often prefer to nest under tall, dense vegetation on some Caribbean islands, but nest on bare or sparsely vegetated sand on many Pacific islands. Even when bare areas are created within vegetated colonies in Culebra, Puerto Rico, Sooties still choose nest-sites under dense cover. Roseate Terns in north-west Europe and north-east North America generally nest under vegetation or in rock crevices, but on the Caribbean islands their nests are exposed on coral rocks, while in Australia they often nest on bare sand with no vegetation cover.

Some terns exhibit a narrower range of habitat preferences. For example, Black Terns (*Chlidonias niger*) usually nest on floating vegetation in marshes, colony sites varying only in the percentage of vegetation cover and its dispersion pattern and in the water depth. In the same habitats Forster's Terns exhibit more variability, nesting on floating vegetation or boards, and on muskrat (*Ondatra zibethicus*) houses. Coastal Forster's nest on exposed mud or wrack on salt-marshes.

Still other species will nest in habitats that seem very different, but are structurally similar. Black Noddies nest either in trees or on cliffs, in both cases elevated sites that prevent the access of ground predators. These habitats also have limited space for nesting, which both increases competition for nest-sites and reduces the level of interspecific interactions. The White Tern is unique in making no nest, instead balancing its single egg on a narrow tree limb or cliff ledge. Many eggs and chicks are lost from such vulnerable sites, and the terns have adapted to more secure perches, including tap or faucet handles where the lip retains the egg even in winds.

The marine distribution of terns is influenced by the availability of food. Most species frequent continental coasts, concentrating particularly in areas of upwelling, at coral reefs, or near estuaries and river mouths: places where aquatic productivity is high. The distribution of pelagic species is little known, but, like most seabirds, they must track patchily distributed foods. Current research, combining satellite tracking of individual birds with acquisition of physical and biological oceanographic data, will greatly increase our understanding of the complex movement patterns of oceanic birds, including those of the terns.

General Habits

Terns are highly gregarious species. They generally breed, forage and migrate in flocks that can range from a few individuals

Terns use a wide variety of habitats for breeding. Many are typical birds of coastal marshes and beaches, with fewer than a dozen regularly nesting inland. The latter include the three "marsh terns" of the genus Chlidonias, *which favour inland lakes, marshes and vegetated riversides for nesting purposes. One of these, the Whiskered Tern, normally nests at well vegetated wetlands in the interior, although locally it may select similar habitats on the coast. After the breeding season most inland breeders move to the coast, where they often associate with other tern species.*

[*Chlidonias hybridus hybridus*, Doñana National Park, Spain. Photo: Günter Ziesler]

to many thousands or even, in the case of Sooty Tern, millions. Most species are diurnal, and a typical day begins at first light when the birds leave their overnight roost or breeding colony to search for food. Whereas many social bird species leave their roost synchronously in large flocks, terns move out from their roosting or breeding colonies solitarily or in small groups. During the breeding season, an individual tern which is not incubating often rests on its territory near its mate. Sooty Terns, and probably other species, feed at night, when bottom-dwelling prey rise to the surface. Foraging terns disperse far and wide, searching for prey either singly or in flocks, or in association with other marine vertebrates. A few feed frequently over land, but only in the Gull-billed Tern is this the usual foraging method.

The activity patterns of terns are affected by a number of factors, including tides, breeding activities, weather conditions, social facilitation and time of day. Terns are often most active in the early morning and late afternoon, whether they are feeding or courting, but the daily activity patterns of coastal-nesting species are often influenced by tidal cycles. Inclement weather can dampen the frequency of courtship and display behaviour, while social facilitation can increase these activities.

Terns are usually short distance foragers over shoals of fish. Within a few hours they can obtain enough food for themselves, and they then return to resting flocks or the breeding colony for a few hours. Those hunting at sea, however, where food is very unevenly distributed, may spend hours simply locating a feeding area. In these circumstances, a bird returning to the breeding site relieves its mate, which then goes out to forage. These incubation bouts range from 20 minutes to more than 20 hours, in Common Terns typically 1-4 hours, after which the mate returns and another change-over occurs. A courting male or a bird with chicks may take slightly longer on a foraging trip, because he must first feed himself, and then catch a large fish to bring to his female or an appropriate-sized fish for his chicks. There is often an increase in foraging activity of both breeding and non-breeding terns in the hour or two before dusk, as they obtain sufficient food for the night; a peak in chick-feeding is generally evident too during late afternoon and at dusk.

Although the tern family breeds from tropical and equatorial regions to both polar areas, most species nest in only one climatic region, which narrows the range of adaptations required. Some, however, such as Little, Least, Common, Gull-billed and particularly Roseate Terns, have both a temperate and a tropical distribution, making their adaptations to thermal stress especially interesting. The Sandwich Tern spans about 100° of latitude, from north Britain and the Baltic to southern South America, while its "Cayenne" race alone spans 60° from the Greater Antilles to Patagonia. Adaptations to heat stress include nesting near rocks or vegetation, as well as gular-fluttering and panting, and behavioural mechanisms such as feather-fluffing and wing-drooping. Some species wet their bellies to reduce heat stress, and return directly to their nests, depositing water on eggs or chicks.

A particularly fascinating and somewhat obscure form of behaviour is sometimes seen at terneries, when some or all of the birds suddenly leave in a dense mass and fly low and silently towards the sea. After a very short time they start to call, and then return singly or in small groups to the colony. These sudden "panics" or "dreads", which seem to be spontaneous, appear to have no obvious cause, but they are thought possibly to be connected with aerial predators. They are most intense in species with the densest nest dispersion.

Voice

The voices of many terns are harsh in quality, and a single call may convey different messages depending more on its context than on its structure. Most terns are noisy, whether on the breeding grounds, while foraging, or while migrating. In the non-breeding season, vocalizations are limited to those associated with flock formation, foraging behaviour and predator avoidance. Even on migration, vocalizations help terns to maintain flock coherence and to find food.

Noise levels in breeding colonies can be very loud, particularly in dense colonies where many adults are mobbing intruders. On the other hand, those species that nest solitarily, in small colonies, or in colonies with widely scattered nests are often very quiet, partly as an anti-predator adaptation. Even species that are noisy when in dense colonies are relatively quiet when they nest in very small colonies or solitarily. For example, Forster's Terns breeding in colonies of 100-150 pairs on salt-marsh islands in New Jersey are quite vocal, but those nesting solitarily in fresh-

One way in which some terns counter heat stress in very hot climates is to moisten their belly feathers and then return directly to their nests, where they are able to wet the eggs or chicks and thus cool them down. Terns not infrequently alight on the water to bathe, but swimming is a remarkably uncommon occurrence among this family of web-footed birds.

[*Sterna antillarum*. Photo: Mike Wilkes/Aquila]

water marshes in Minnesota are usually silent; even those dispersed within Franklin's Gull (*Larus pipixcan*) colonies are usually silent unless an intruder comes within a few metres of their nests.

Terns have a wide variety of vocalizations that are used during the breeding season: when defending territories, soliciting mates, engaging in courtship behaviour, maintaining the pair-bond, exchanging incubation duties, and communicating with their chicks. Although interspecific variations exist in the nature of the calls, most terns have variants of some common call types. When flying around the colony or arriving with fish they often give a "che-wick" or "kiewick". In aggressive interactions they will give a "keek, keek, keek" or a "keow, keow", both to conspecifics and to other intruders. During high-intensity interactions this call is shortened to a frantic "kek k k k k k". The "Rattle" call too is used to repel conspecific intruders.

Vocalizations are an integral part of courtship, again with interspecific differences. For those species that have fish-flights (see Breeding), the first bird to depart, usually the male, may utter a "kearr, kearr, kearr" call, the partner will give a "ki ki ki ki ki", and the male will answer with a "kor kor kor korrrrr". All terns have a copulation call: the male gives a repetitive "kuk kuk kuk", undulating in quality, and repeated for the duration of copulation.

Food and Feeding

Although terns are generalists with regard to nesting habitat, they are more specialized foragers than are gulls. They are not, however, complete specialists: there is no species of tern that feeds by only one method, in only one habitat zone, or on only one prey. Apart from the Gull-billed Tern, which feeds over terrestrial habitats, most terns obtain most of their food from aquatic habitats, either freshwater, estuarine or oceanic. The Kerguelen Tern feeds largely on insects over uplands during the breeding season, but on aquatic prey during the rest of the year. During the breeding season some of the marsh terns specialize in foraging over freshwater lakes or marshes or over coastal marshes; they search for prey over open or sparsely vegetated water, although they sometimes capture aerial insects over marshland. Terns feed on a large variety of small, usually schooling, fish, and congregate when large shoals are discovered. Hence, when two or more tern species occur together, they are likely to exploit the same food resources, as these are temporally and spatially patchy.

Coastal breeders usually forage from tidal creeks and estuaries to ocean waters, usually close inshore, but occasionally ranging across the continental shelf. Most species prefer to fish in sheltered bays and lagoons, since rough water depresses their success. Those nesting on oceanic islands either forage along the fringe of the island, or travel far offshore to forage in the open ocean. Sooty Terns often do not hunt near the colony, but may fly up to 100 km or more over the open ocean.

All the foraging methods used by terns involve skill, grace and agility in flight. A dense flock of Common Terns or Black Noddies foraging over a compact school of fish forced to the surface by larger predatory fish is one of the most aesthetic of coastal spectacles, and the graceful swooping and soaring flight of Sooty Terns as they head out to the open ocean is equally breathtaking. In inland marshes, the dark silhouette of a Black Tern swooping through a brilliant blue sky to the still waters of a pool surrounded by gently waving cat-tails or reeds is riveting.

Although typical and crested terns generally feed by plunge-diving for fish over water, most are capable of using a variety of

It is very important for all birds to keep their plumage in excellent condition, as their success and survival frequently depend directly on it. This is particularly true of such aerial birds as terns. Despite their very short legs, terns are able to walk well on land, although they are noticeably less mobile than gulls. Note the darkish grey upperparts of this preening Greater Crested Tern, one of the main features of geographical variation in this species.

[*Thalasseus bergii velox*, Nafoon, Oman. Photo: Hanne & Jens Eriksen/Aquila]

In territorial defence against conspecifics, terns walk or fly towards opponents, and indulge in fights and aerial chases. Particularly characteristic of some species, such as the Arctic Tern, is the "upward flutter flight". This is used in hostile encounters, often between neighbouring pairs: the birds rise in half-hovering flight, sometimes high into the air, periodically flying at one another bill-first.

[*Sterna paradisaea*, Churchill, Manitoba, Canada. Photo: Arthur Morris/ Birds As Art]

methods. These include contact-dipping, aerial-dipping, hover-dipping, surface-dipping, aerial hawking for insects, and piracy from their own or other species. Some species, such as the Sooty Tern, do not plunge-dive.

Plunge-diving involves quartering back and forth at a height of 3-15 m while searching for prey below the water's surface, hovering over the prey to fix its location, and plunging directly into the water, sometimes after a stall or even a brief upward movement. The tern generally submerges completely, although sometimes, if prey are near the surface, only the bill and head will be immersed. Terns sometimes even pursue their prey for a short distance under water, where their swimming movements resemble those used in flight. In most cases, however, they submerge, pick up the fish with the bill, and immediately leave the water and rise up into the air. This foraging method requires great skill and agility, since birds must compensate for refractive properties of the air-water interface, while they and their prey are both in motion.

Contact-dipping involves flying closer to the water, swooping down, and plunging the bill alone beneath the surface. It is particularly appropriate when there are many food items near the surface, since a tern can contact-dip repeatedly with no interruption in feeding, while plunge-diving is necessary for fish more than a few centimetres below the surface. Aerial-dipping is the same as contact-dipping, but without any contact being made with the water.

Hover-dipping entails hovering about 1-2 m above the water, and dropping down to seize items from the surface. Sometimes this method is combined with foot-paddling to stir up prey items.

Surface-dipping, unusual for most terns, involves sitting or swimming on the water and picking up items from the surface or from just below it. Some terns sometimes forage on mudflats by walking, gull-like, and stabbing at prey.

In aerial pursuit or hawking, a tern wheels and circles in the air to catch insects which have just emerged in vast numbers, often over freshwater marshes. Forster's, Black and Common Terns regularly engage in this type of foraging, and many others use it less frequently.

Many tern species forage in association with other marine organisms, such as porpoises (*Phocoena*) and predatory fish which drive schools of small fish and concentrate them near the surface. Examples include Common and Roseate Terns over bluefish (*Pomatomus saltatrix*) in the Atlantic; noddies, Great Crested, Lesser Crested (*Thalasseus bengalensis*), Roseate and Bridled Terns over tuna (*Neothunnus macropterus*) and bonito (*Euthunnus affinus*) in Australian waters; and Black-naped and Roseate Terns foraging over schools being pursued by Spanish mackerel (*Scomberomorus commersoni*) off Africa. In the northern tropical Pacific, Sooty Terns, noddies and White Terns feed together with the combined schools of tuna and dolphins, while in the southern tropical Pacific mostly single-species flocks of Sooty Terns feed over small tuna only seldom accompanied by dolphins.

Piracy is another common foraging method, usually practised at breeding colonies, where a steady stream of fish is brought in by males courtship-feeding their mates, or by parents feeding chicks. Terns pirate fish from their own species as well as from others. Conversely, they are often victimized by larger birds, particularly gulls and skuas. Some tern species are extensively targeted by other pirates: Arctic Skuas (*Stercorarius parasiticus*), for example, rely heavily on piracy of terns, and may accompany Arctic Terns on migration so as to continue to exploit them.

Terns also exhibit a variety of unusual foraging methods. Common Terns wintering off Peru aerial-dip towards wet sand to pick up mole crabs (*Eremita analoga*) behind receding waves. Bridled Terns in Japan and Kerguelen Terns will forage for small fish and invertebrates associated with drifting seaweed. Several species follow the plough, although this feeding method is not nearly so important as it is for gulls. Least Terns will pick up fish from a fisherman's bucket, and several species follow fishing boats or patrol the shoreline to pick up offal discarded by fishermen. Roseate Terns and Brown Noddies feed in association with Brown Pelicans (*Pelecanus occidentalis*), hovering over a pelican as it emerges and snatching fish that fall from its bill.

Except for the mainly insectivorous and lizard-eating Gull-billed Tern, all species rely primarily on aquatic organisms, mainly fish, for their food. Many terns also eat crustaceans, and some freshwater species opportunistically take frogs and tadpoles. Gull-billed Terns forage extensively over agricultural fields, and grasshoppers often constitute an important part of their diet; this species also eats frogs and crabs.

The size of prey taken is determined largely by the size and width of the tern species' bill: larger terns, with a larger bill and wider gape, can consume larger fish. It also varies according to prey availability, breeding phenology, and the prevalence of pirates; larger fish are more vulnerable to piratic attempts. The species composition and size of fish present vary seasonally, and birds must sample from the available pool or travel further to find more adequate prey.

Age-related differences in foraging ability have been found in nearly all terns for which this aspect has been examined. Birds of the year are less efficient at locating feeding sites, at attempting to catch prey, and at actually catching prey once they make an attempt. Presumably, the difficulties of learning to forage account for delayed first breeding. Sooty Terns, which sometimes do not breed until they are 6-10 years old, have to be capable of finding very patchily distributed prey in the open ocean.

Breeding

Terns are normally monogamous, although other mating systems have been recorded. Trios or female-female pairs, or both, have been observed only in the Caspian, Roseate and Common Terns, although supernormal clutches have been used as an index of female-female pairs. Such clutches have been reported in the literature and from museum collections for Gull-billed, Caspian, Elegant, Sandwich, Royal, Roseate, Black-naped, Common, Arctic, Forster's, Least, Sooty, Black-fronted and Black Terns and Brown Noddy. However, these data must be interpreted carefully, because: egg-collectors may have prized large clutches, leading to bias in the frequency of supernormal clutches in museum collections; in colonies with small distances between nests, eggs can be rolled into other nests; and in marsh colonies, eggs flooded out of one nest can be retrieved into another by nearby nest-owners. This last phenomenon has been documented at nests of Common and Forster's Terns, where marked eggs were checked before and after floods.

Terns are among the noisiest of birds, their voices in most cases being very harsh and grating. One of the loudest and harshest of all vocalizations is the rasping call of the Caspian Tern. The vocal repertoire of terns is widest during the breeding season, with different sounds being used in relation to mate-soliciting, courtship and pair-bonding activities, territorial defence, change-overs at the nest, and communication with chicks. Some call types are common to most species, with relatively minor variations. A single call can convey different messages, depending on the context in which it is given.

[*Hydroprogne caspia*, Sweden. Photo: Bengt Lundberg/ Bios]

Hybridization is rare among terns, but has been recorded between Roseate and Common Terns in Europe and North America. Mixed pairings have also been found in Europe involving Sandwich x Lesser Crested, Sandwich x Elegant, the latter a presumed vagrant, and Black x White-winged (*Chlidonias leucopterus*) Terns.

Most terns exhibit an annual cycle, in which they breed once annually, at approximately the same time of year. The breeding season may last 2½-3 months for Arctic species, 3-4 months for temperate species, and 3-5 months for tropical species. It is extremely rare for a pair of terns to raise more than one brood in a single cycle.

In a few tern populations with an annual cycle, breeding is not synchronous among colony members, while some tropical terns, notably the Sooty, do not exhibit an annual breeding cycle at all. In both cases, some breeding may occur in all months of the year at a given colony, as on some tropical islands. On Christmas Island in the Pacific Ocean, the breeding cycle of White Terns lasts up to 10½ months for successful birds, but is shorter for unsuccessful ones; moult always takes 5½-7 months, so failed breeders nest out of synchrony. The so-called "Wideawake Fairs" or mass breedings of Sooty Terns occur at intervals of about 9·6 months on Ascension Island and at intervals of 6 or 7 months on Christmas Island, although in the Caribbean the species has an annual cycle. On Ascension Island, there are Sooty Terns and Black Noddies breeding at all times of the year. For most Bridled Terns there is a well defined annual breeding cycle at the same time each year, but in the Seychelles the breeding cycle lasts 7-8 months.

Documentation of age at first breeding benefits from long-term ringing studies, which have so far involved relatively few species. Although some individuals of the small and intermediate-sized terns first breed when they are two years old, most do not breed until three years and some not until four. Some species, such as the Bridled Tern, regularly breed only when they are four years old, although individuals come back to the colony at two and three years of age. The larger species do not breed until they are three, four or five years of age, and some species do not regularly breed until they are still older. Sooty Terns at Johnston Atoll breed at four years, but some wait until they are six to eight or even ten years old. Presumably, this delay is because young terns must master the difficult foraging and feeding techniques. Some studies show evidence of assortative mating by age, young birds tending to pair with birds of a similar age, but whether this reflects a true preference or simply the age distribution of available mates requires study.

In the vast majority of cases terns are colonial, sometimes forming huge agglomerations. Many species occupy the same colony site for many years, whereas some others, such as Little and Least Terns, often change sites after only one or a few seasons. Colonies are abandoned when the site becomes unsuitable because of habitat change, frequent human disturbance, predation, or weather stresses such as severe storms or floods. In general, the sites that have been used for the longest periods of time are isolated coastal or inland islands or remote oceanic islands, where the threat from predators and human visitors is low. Sooty Terns have apparently occupied certain oceanic islands for several centuries.

Faithfulness to a nesting site, or philopatry, varies according to habitat stability. Species that nest on cliffs and remote oceanic islands can occupy the same colony site for years, since the habitat is stable. Habitats that change from year to year, such as freshwater marshes, riverine sandbars and coastal sand spits, may be used for only a few years or even a single year. Terns return to their previous site, assess its suitability, and then either occupy the site or move elsewhere. Those which normally nest in unstable environments often exhibit group adherence: the members of the group, subcolony or small colony remain together, even though they may shift colony sites.

Terneries range in size from a few pairs to many thousands. In the colonies of some species, such as the Damara Tern, the nests are so widely spaced that they can be considered solitary, but the distribution of pairs is nonetheless clumped. Some true solitary nesting does occur, and, moreover, a single pair of one species will nest in a colony of other terns or gulls. Species such as the Black-bellied Tern (*Sterna acuticauda*) and the Yellow-billed Tern nest in small colonies of only a few to a dozen pairs, with inter-nest distances ranging up to 1000 m. Interme-

In keeping with their social habits, terns are often seen foraging in flocks. Common Terns frequently gather in large numbers to exploit food sources, and are quick to spot any shoals of small fish that may appear in inshore waters. The feeding method perhaps most closely associated with terns is plunge-diving, and this is indeed the commonest method employed by most of the typical Sterna *terns and by the "crested terns" of the genus* Thalasseus. *Virtually all terns do, however, use a variety of tactics for capturing food, all of which call for great agility and skill in flight. Besides plunge-diving, they frequently indulge in contact-dipping, in which they swoop down towards the water and catch food items by dipping the bill just below the surface, without making any other contact with the water; surface-dipping, involving swimming on the water and picking items from on or just below the surface, is far less common. In addition, several species, among them the Common Tern, are highly skilled at hawking aerial insects, and they also steal food from other terns.*

[*Sterna hirundo hirundo*, Norfolk, England. Photo: Roger Tidman/ NHPA]

With very few exceptions, terns obtain most of their food from freshwater or saltwater habitats. Fish and aquatic invertebrates form the bulk of the diet of many species. Having seized an item following a plunge-dive, which generally involves complete, though brief, submersion, the tern immediately leaves the water and rises into the air. The strike rate has been found to be higher among adult terns than among immatures, which have to learn the skills required for efficient foraging.

[*Sterna hirundo*.
Photo: Åke Lindau/Ardea]

diate-sized terns generally nest in colonies of tens or twenties to several hundred pairs. An exception is the Sooty Tern, which occupies colonies containing several hundred to several thousand pairs, and occasionally up to two million pairs. Colonies of crested terns normally hold hundreds and occasionally thousands of pairs.

Nesting dispersion also varies. Sooty Tern and various crested terns regularly breed in very dense colonies only a body length apart, while other species nest in very loose colonies. Unlike the situation with gulls, inter-nest distance in terneries decreases with increasing size of the tern species. The larger species, such as the Caspian, Royal, Great Crested and Sandwich, form very dense colonies, where an incubating bird can almost reach its neighbour. Colonies of the intermediate-sized terns, such as Common, Roseate, Arctic, Forster's and the noddies, are fairly dense, with nests 1-5 m apart. The small terns often nest in fairly loose colonies in which distances between nests may be 5-100 m or more. All tern species are territorial, although the size of the territory and the intensity with which it is defended vary. Territory size determines the pattern of nest dispersion within colonies, which is itself partly a function of competition and anti-predator strategy.

When taking occupation of the site, the larger species can displace nesting gulls from parts of their colony by entering *en masse* and setting up territories; even the larger gulls soon abandon their eggs when faced with so many large terns. In this way Caspian Terns displace nesting Herring Gulls (*Larus argentatus*) in the Great Lakes of North America, Royal or Sandwich Terns displace Laughing Gulls (*Larus atricilla*) along the Atlantic coast of North America, Sandwich Terns displace Black-headed Gulls (*Larus ridibundus*) in Europe, and Elegant Terns displace Heermann's Gulls (*Larus heermanni*) in the Gulf of California.

In Puerto Rico, Royal and Sandwich Terns, two species which regularly associate with each other, often nest in adjacent, but dense colonies. Late-arriving potential competitors for nesting space find it difficult to enter such a dense colony of large terns, and are relegated to nesting on the edge. Colonies thus expand in size during a breeding season.

The larger terns also rely on their nesting pattern to prevent aerial predators from getting within the colony. With the dense packing and noisy commotion of a Caspian, Royal or Sandwich Tern colony, aerial predators can not find a suitable place to land, and it is difficult to enter from the edge.

Intermediate-sized terns and some of the small terns, however, rely on behaviour such as mobbing and aerial attacks to repel predators. They repeatedly swoop low overhead, one after the other, often striking with the bill, and sometimes even killing predators. Even casual human intruders are discouraged by such mobbing, although it is ineffective against eggers or other determined humans. These terns also rely on the cryptic coloration of their eggs and chicks to reduce the likelihood of predation, a strategy that is most successful if the eggs or chicks are not close together; this is, indeed, the case, since the nests of these terns are well spaced.

Peruvian and Damara Terns nest in very small colonies in which pairs are often 100 m or more apart, the cryptic coloration of their chicks and eggs helping to prevent ground or aerial predators from finding their nests. They do, however, nest close enough to be in vocal communication, which allows for early warning and mobbing of predators.

Predation pressures can affect nesting dispersion. In a Least Tern colony in New Jersey, USA, inter-nest distances increased dramatically following intense fox (*Vulpes fulva*) predation. The nests remained widely spaced for several years while the predators were still present, and coalesced into a denser colony only after the foxes were controlled.

Although some terns breed in monospecific colonies, many nest with other species of terns, as well as with gulls, skimmers, boobies, alcids, ducks, and even sea turtles. In some instances the terns select the colony site after the other species is already nesting, but in many cases the latter is attracted to the terneries, gaining benefit from the terns' aggressive mobbing. For example, Forster's and Black Terns often select nest-sites and begin egg-laying within Franklin's Gull colonies only after the gulls have laid. In this case, the tern species are smaller than the gulls but derive protection from them, as the gulls mob and attack aerial predators such as hawks. The terns, present in small numbers, also benefit from a "swamping" effect, since they are thus only a few among many thousands of colony members.

Terns will also nest beside colonies of albatrosses, cormorants, and any other seabirds that nest within their range. In many of these cases, however, the terns are not choosing to nest with the other species, but rather both species are selecting the same remote, suitable breeding site. Often, such sites are in limited availability.

Terns usually spend a few weeks in the vicinity of the colony before taking up residence. During this time they may fly over

Terneries vary in size and in density. Colonies of the larger Thalasseus *"crested terns" contain hundreds and not uncommonly thousands of pairs, which are normally very densely packed together. In contrast to the pattern in gulls, the inter-nest distance decreases with increasing size of the tern species. Royal Terns, for example, form colonies that are often very large and almost always very dense, with up to 8 nests/m². Such a dense assembly of birds makes it difficult for a predator to land within the colony.*

[*Thalasseus maximus maximus*, Baja California. Photo: Ramón Torres Valdivia]

the colony during the day, or stand in clubs or courting groups. Attendance at the colony gradually increases, and the birds then begin to establish territories. The normal phenology of temperate zone species is to select territories, defend them, solicit mates or re-establish pair-bonds with mates from the previous year, engage in courtship and courtship feeding for a few days or weeks, followed by an egg-laying period of a few days to two or three weeks, an incubation period of 21-28 days, and a chick-rearing phase or fledging period of about four weeks. Depending on the degree of synchrony within a colony, egg-laying may extend over a period of two months, with later laying due to failures or the influx of new, usually young, birds. These time periods may be slightly shorter for the smaller terns, and slightly longer for the larger ones. This schedule basically applies to temperate- and Arctic-nesting species, with activities generally more synchronous at high latitudes. Tropical terns, however, have adapted to the lower food availability by prolonging each phase.

The detailed activities during each of these phases vary with species and locality, and are greatly influenced by food availability and weather. Common Terns provide a basic example. Early in the breeding cycle, they gather in small groups on the colony, mainly at night, sometimes huddled against the cold; they may be absent during the day, or a few distant notes may be heard from birds flying high overhead. Gradually the terns spend time on the colony during the day, at first landing for a few minutes and then staying for longer periods. They select territories, and spread out in the available habitat. Factors determining their territory selection include both physical features of the habitat, such as vegetation structure and density, and social factors, such as the presence of conspecifics or other species. Unmated males defend their territories while they solicit for mates, and mated pairs defend their territories and engage in re-establishing pair-bonds. Some unmated males shift their territories from one place to another within the colony, hoping to attract females, while others fly above the colony, searching for mated females that they can steal from other males or unmated females that they can court.

Normal territorial defence against conspecifics involves walking or flying towards opponents, aerial chases, "upward flutter flights" and ground and aerial fights, as well as a number of displays, including "Oblique", "Crouch" and "Gape" displays. In an aggressive encounter, a tern may initially give a "Head-toss", followed by "Up-erect" with head-turning for insecure birds, and by "Down-erect" for secure birds. In appeasement, a bird may give a "Head-nod", "Head-tilt" or "Head-turning", all equivalent to "Facing-away" in gulls.

Normal courtship and pair-bonding involve a variety of highly ritualized displays, performed on the ground and in the air. In many species, courtship sequences are initiated when the male brings back a fish; he may offer this to the female, and she may either swallow it immediately or keep it in her bill during the display.

During this courtship period, both mated and unmated birds engage in aerial "high-flight" displays or "fish-flights". These typically begin when a male brings back a fish to a female; almost immediately after he lands, both take off and fly high in the air, in tandem, often alternating with gliding on rigid wings. One or two other birds frequently join in these fish-flights. Most terns have a high-flight, although some do not have so elaborate or so ritualized a fish-flight as do the Common, Roseate, Least or Arctic Terns. In some the high-flight is similar to the fish-flight, and in others the two displays differ. The Caspian Tern's high-flight differs from that of both the crested terns and the typical terns, supporting its separate generic status.

Once pairs have formed, the frequency and intensity of courtship displays accelerates, with the addition of courtship feeding. During this period the female often remains on the territory, defending it against intruders, while the male spends all day bringing back fish to feed her. When pairs are firmly established, either the male departs immediately after giving her the fish, or copulation follows fish-transfer without the intense and prolonged courtship displays.

Prior to copulation, courting pairs circle around each other, often with wings slightly drooped and bill pointed downwards. The male points the bill up in a full "Upright" display similar to that of gulls, while calling softly. For several minutes the two may dance around each other, calling softly, with their wings drooped. Copulation often follows such displays. A receptive female crouches, and the male hops onto her back. This copulatory stance may occur several times before cloacal contact is achieved, and birds sometimes maintain this position for many minutes. At the time of contact, the male raises his wings in "copulatory wing-flagging" to achieve balance and lowers his tail to one side, the female simultaneously raising hers to the other side. Cloacal contact lasts a few seconds, and is usually followed by the male dismounting. A pair may mate many times in a day

Courtship feeding is an integral part of the breeding ritual of terns, serving the important function of reinforcing the pair-bond. It may continue for some days or even weeks before egg-laying begins, and the male may appear to spend most of his time during this period bringing fish to the female. Although most tern species usually carry back only one fish at a time in the bill, whether for courtship feeding or to provision the chicks, White Terns regularly return with three or more fish lined up in the bill. If the male offers the fish to the female, as in the case of these Forster's Terns in the second photo, she may either swallow it or hold it in her bill. In the early stages of courtship, the next step can be a "high-flight" or "fish-flight" display, in which both birds fly high in the air, intermittently gliding, and often being joined by one or two other individuals. Once pairs are firmly established, either the male leaves immediately after presenting the fish, or copulation follows. The amount of courtship feeding is thought to help the female to judge the quality of her mate; if he seems to be a poor provider, she may leave him early in the breeding cycle and mate with a "better" male.

A receptive female Common Tern crouches and the male hops on, but several attempts may be required before cloacal contact is achieved; terns sometimes maintain this position for some minutes. The male balances by raising his wings and lowering his tail to one side, the female raising her tail to the other side; cloacal contact is very brief, before the male dismounts. A pair of terns may mate many times in a day. Copulation is often preceded by the two birds circling around each other with wings drooped and bill pointed down. As with gulls, this display and "wing-flagging" during copulation may act as signals to other pairs in the colony, leading to synchronous mating.

[*Sterna hirundo hirundo*, Long Island, New York, USA. Photo: Tom Vezo]

prior to egg-laying. The pre-copulatory circling display and the wing-flagging often appear to serve as a signal to other pairs, and there is evidence of synchronous matings in several species.

During courtship through to incubation, a male Common Tern will bring back up to five or six fish an hour for his mate. The amount of courtship feeding is believed to help the female to judge the quality of her mate, and early in the cycle a female may leave a mate which shows signs of being a poor provider. The frequency of feeding declines somewhat during incubation, as the female does more fishing on her own. At this time, piracy increases in frequency and intensity, and males must balance the rewards of bringing back particularly large fish against the increased risk of piracy. The rates of both attempted and successful piracy increase with the size of the fish; as the fish are carried in the tern's bill they are visible, and pirates can therefore choose to pursue terns carrying large fish.

Nest-site selection occurs during the period immediately before laying, since most terns except tree-nesting noddies and marsh-nesting species make little or no nest. Both members of the pair engage in scrape-making, and species with relatively large territories may make several scrapes before agreeing on a given location. In the densest terneries the nest-site is determined by its position in relation to neighbours. The "Scrape" and "Bent" displays are amongst the pair-maintenance displays.

Marsh-nesting terns, such as Forster's, Trudeau's, the Black, Whiskered (*Chlidonias hybridus*) and White-winged, must construct a floating nest out of the available vegetation. During courtship and territory acquisition they must find a suitable platform for displaying, and this often amounts to only a few stems matted together from winter storms. During the territory defence phase, both sexes may add material until it becomes a sturdy nest platform. They then begin to fashion a cup by swaying and settling their bodies in the vegetation, in much the same way as beach-nesting terns fashion a cup in the sand.

Tree-nesting species, such as the White Tern, must select a particularly stable branch for the egg and chick, and Black and Lesser Noddies must select a place where they can build a nest of twigs, feathers and excreta. By not building a nest, White Terns may reduce the parasite load for their chicks, but the loss of wind-blown eggs and chicks is great. Cliff- or ledge-nesting species, such as Brown Noddies, often move the small coral rubble to the edge of the cliff, providing a smooth surface for the eggs and chicks, and a slight lip to prevent the egg from rolling off.

Clutch size varies among species. For instance, Royal, Elegant, White-fronted (*Sterna striata*) and Sooty Terns and Brown and Black Noddies lay one egg; Caspian, Roseate, Arctic, Sandwich and Least Terns lay two; and Gull-billed and Common lay three eggs. For species that normally lay two or three eggs, clutch size is dependent on food supply. When this is low, it can reduce the average clutch size to one or two eggs, and can also increase the laying interval between eggs. In bad food years, Roseate Terns will lay only one egg and Common Terns only two. Species that lay only one egg have the option in bad food years of not laying, or of delaying breeding, or they may lay smaller eggs; smaller eggs, however, produce smaller chicks, which in general have lower survival rates. By contrast, clutch size can be increased in good food years, as apparently happened with Arctic Terns in the Baltic in 1989 and 1990. In species laying more than one egg, average clutch size normally decreases through the season, and replacement clutches are often smaller. As with gulls, supernormal clutches of five or more eggs are often the result of more than one female at a nest, in the form of trios or female-female pairs. In dense colonies, however, a bird may roll neighbouring eggs into its own nest, particularly if the eggs have been displaced by flooding.

Both members of the pair engage in territory defence and incubation, and both brood, feed and defend the chicks. In most species studied in detail, females perform somewhat more than half of the incubation, and males do more of the chick-feeding in the week following hatching. Aggression peaks during the hatching period, when the small chicks are most vulnerable, remains high when the chicks are small, and gradually decreases as they approach fledging. By that time the colony thins out, as early or failed pairs leave.

Territories of ground- and marsh-nesting species may shrink slightly during incubation, as the efforts of the pair are directed towards protecting the eggs. Nonetheless, both members of the pair will defend against intruders that are still searching for territories, although neighbours are often ignored. For cliff- and tree-nesting terns the territory is often limited to the ledge or area immediately around the nest, since it is difficult for intruders to land close by. However, species such as noddies that nest in dense-

limbed trees, often have a number of close neighbours, and territorial squabbles may be frequent, both between neighbours and with intruders that are trying to claim a new nest-site. These tree-nesting species show no evidence of recognizing their own eggs or chicks.

Most terneries are subject to breezy or windy conditions, and there is a strong tendency for all incubating birds to face the same direction, into the wind. Incubation can involve sitting on the eggs 100% of the time in Arctic and temperate environments. In tropical regions, terns incubate during the night and early morning, stand to shade the egg in the hot part of the day, and incubate again in the late afternoon and evening. In extremely hot environments, they may resort to flying to nearby waters to wet their bellies, and may return to the nest to wet the eggs or chicks to reduce heat stress.

For most terns incubation usually lasts 21-28 days, although for some tropical species it is more prolonged. The length of incubation bouts depends on how far adults must travel for food and its availability once they get there. At some colonies, Sooty Terns may travel over 100 km to feeding areas, and incubation stints often exceed 24 hours, reaching six days at Ascension Island. Stints of 1-3 hours are typical of most species, although Black Terns and Least Terns may make two or more change-overs per hour when feeding close to the colony.

The hatching process generally takes more than a day, and during this time parents are particularly protective of their eggs, increasing their mobbing activities. Chicks hatch using an egg tooth on the upper or both mandibles, and gradually lose this by day 5. Terns that lay three eggs usually start incubating after the second egg is laid, so the first two eggs hatch within a few hours of one another. The third egg may hatch a day or two later, giving the chick a decided disadvantage in terms of size, weight and strength when competing with its siblings for food; moreover, the third egg is usually smaller than the others, adding to its size disadvantage. In general, chicks hatching from larger eggs do better, primarily because of the higher protein content, which influences vigour and survival. Consequently, survival to fledging is usually lower in third-hatched chicks. One method third chicks have of combating competition with their siblings is to seek adoption in nearby broods; in such cases they are more likely to be successful if they join one- or two-chick broods, and if they are older than the youngest chick in the adoptive brood.

Young chicks spend more than 80% of their time inactive, usually crouched in the nest or in nearby shelter, waiting for the parents to arrive with food. Better-fed, faster-growing chicks spend more time preening, walking, and attacking neighbouring chicks. In most high latitude terns, and in some tropical species, the chicks are fed several times a day or even several times an hour. The parent brings back fish, shrimps or other invertebrates in its bill, and extends it to the chicks. A chick seizes the food at a point near the parent's bill, and, with a series of upward jerks of its body and head, manipulates the fish until the head is in its gullet; it then jerks its head again until the fish is swallowed. With relatively large fish, a tiny chick must heave itself backwards with all its strength, and if it pauses to rest it may lose its fish to an alert pirate or a larger sibling. In broods of two or three chicks there is competition for the food, and fights often occur.

The young of some tropical terns are fed less regularly, and their growth rate reflects this difference in the adults' foraging pattern. The chicks of inshore foragers generally grow faster than those of more pelagic species, the latter being limited by the ability of their parents to transport prey from the foraging grounds to the breeding colonies. This is true for chicks of inshore-feeding Black-naped Terns breeding on islands in the Great Barrier Reef: their growth rate is faster than that of the more pelagic-feeding Great Crested Terns nesting on the same islands.

Although most tern species usually bring back one fish per trip, making many trips a day, Roseate and Common Terns occasionally bring several fish at a time, the record being eight. White Terns regularly return with three or more fish lined up in their bills. Sooty, Bridled and Grey-backed Terns and the dark noddies, however, are not known to carry fish in the bill, but they bring back several fish in the stomach and crop and regurgitate these directly into the chick's bill; in this way they may transport many fish and make far fewer trips per day. Interestingly, since the adult swallows these fish head-first and regurgitates them tail-first, the chicks swallow them tail-first. Some studies have shown a tendency for the size of fish brought to chicks to increase as the chicks grow, but this may reflect prey availability rather than selection.

As with gulls, the onset of parent-young recognition is associated with chick mobility. Chicks of most ground-nesting species begin to move out of the nest at 2-4 days of age, while those of marsh-nesters will stay in the nest for two weeks, and tree and cliff nesters until fledging. Forster's Tern chicks raised in dry land colonies exhibit mobility at the same age as ground-nesting species, despite the fact that most Forster's Terns nest in marshes.

As chicks grow older, there are two patterns of behaviour: crèching and non-crèching. Crèches are characteristic of all crested terns and the Sooty Tern. If their colonies are disturbed, the chicks leave their nests early and form crèches a week or more before they would do so in undisturbed colonies. The

Most terns nest on the ground, selecting the nest-site just before the egg-laying phase. The nest itself is no more than a shallow, unlined scrape in the ground. Clutch size varies, but for many, including the White-cheeked Tern, it normally consists of two or three eggs. When the species' food supply is poor, however, it has the option of reducing the number of eggs it lays.

[*Sterna repressa*.

The incubation period for terns is generally 21-28 days, and both parents share duties. Change-overs normally take place every few hours, but the length of a single bout of incubation depends on the distance to the feeding grounds and the time it takes to forage successfully. The Arctic Tern prefers to forage fairly close to the colony, but it may at times have to travel much farther, leading to much lengthier incubation stints.

[*Sterna paradisaea*, Greenland. Photo: Hubert Klein/Bios]

crèche is a large, dense group of chicks, a tight herd attended by only a few adults. The entire crèche moves away from intruders as a unit, creating the illusion of a giant amoeboid creature. During this period, both parents are normally away from the colony on foraging trips, and when they return they call their chicks from the crèche for feeding. Crèching evolved as an anti-predator strategy for times when the parents are not present to defend their young; the chicks derive early warning, and benefit from a swamping effect through being in a large dense mass of birds.

Most typical species of ground-nesting terns, such as Common, Roseate, Arctic, Least and Little Terns, do not form crèches. Instead, the chicks remain at the nest-site or on their natal territory, and are normally guarded by one or both parents throughout the brooding phase. As they grow, they begin to defend their territory against intruding chicks or even adults. If disturbed, they may run or be led by their parents to secure areas outside the colony.

In terns that form crèches, and in species where the chicks wander away from the territory, parents are able to recognize their own eggs and chicks. Even when a crèche has formed, they feed only their own offspring. For some species, such as the Caspian Tern, recognition is at least partly by down colour and pattern; in others, voice plays a role. Parental recognition of chicks usually develops at the time when chicks begin to move away from the nest; chicks learn to recognize their parents at about the same age. Tree-nesting noddies do not recognize their young if they are out of the nest.

Food piracy, although not recorded for several species, occurs regularly at Common, Arctic, Roseate and Least Tern colonies. Much of this piracy involves conspecifics. Depending upon the nesting assemblage at the colony site, terns can be either the pirates or the victims, or they can be both. In temperate and Arctic regions gulls are often the pirates, and are usually successful against the smaller terns. In tropical colonies the pirates are usually frigatebirds, and on Caribbean islands Laughing Gulls.

Piracy rates vary during the breeding season, being highest during courtship feeding and the brooding phase, when the terns are bringing the most fish back to the colony. Pirates preferentially chase, and are also more successful against, terns carrying large fish. Thus, in colonies with intense piracy pressure, terns try to reduce the risks by bringing back slightly smaller fish and flying lower over the colony, making piracy more difficult.

Both adults and neighbouring chicks will try to pirate fish during the transfer from parent to young, and while chicks are trying to swallow particularly large fish. In some species, parents feed small fish to small chicks, gradually increasing the fish size as chicks grow and are able to swallow the larger meal quickly.

A notable feature of many terneries is their active defence against predators. This includes early warning by vocalizations, mobbing and harassment of predators, and direct attacks on predators. Terns will also mob and attack human beings entering their colonies. In general, the frequency of mobbing is highest at hatching and when the chicks are small, and decreases thereafter. It is common among terns that do not form crèches, such as Common, Arctic, Roseate, Little, Least, Bridled, Black-naped and Sooty, as well as in Great Crested Terns, although the intensity of actual attacks varies.

At some colonies, the larger species, such as Caspian, Royal, Great Crested and Sandwich Terns, defend their eggs and chicks by sitting tightly on them. Adults then threaten predators with open bill and erect feathers, and by uttering an aggressive "gak gak gak" or a screaming call. The difference in defence between species of terns relates to the threat the potential predator poses to the adults themselves: smaller terns are more vulnerable than larger terns, and usually do not remain on the nest when predators are near. Peruvian Terns leave when an intruder is still very far off, and do not mob. Predators themselves can use mobbing intensity as a clue to a nest's location. Least Terns occasionally give a very weak distraction display, landing a short distance from the nest, making short, weak hopping flights, and even collapsing for a moment, but these are nothing like the distraction displays of many shorebirds.

The territory and colony site are usually abandoned only a few days after the chicks fledge, but in some species, such as the Common Tern, the family may continue to use the nest-site, returning there for the purpose of feeding fledglings. Terns typically disperse with their young to surrounding areas, and in many cases they show a brief dispersal in the direction opposite to that of migration, for example in the Northern Hemisphere moving some distance northward. Within a few weeks they leave the vicinity of the colony and migrate to wintering grounds. The juveniles may remain with their parents for many weeks or months, their dependence on them for food slowly decreasing. After a few months on the wintering grounds, the terns migrate back to the vicinity of the breeding colony, before beginning to settle for another breeding attempt.

Measures of productivity, such as clutch size, hatching rate and fledging rate, are often related to colony size. Birds in large colonies do better than those in small ones, and this is even true of Gull-billed Terns, which usually breed in colonies of fewer

Young tern chicks spend most of their time crouched in or near the nest, awaiting their parents' arrival with food. In three-egg clutches, the third egg is usually smaller; since incubation begins with the laying of the second egg, the hatching of the third may also be delayed by a day or two. The third chick is therefore at a great disadvantage when competing for food with its larger and stronger siblings, and survival to fledging is generally lower for third-hatched chicks.

[*Chlidonias niger niger*. Photo: Oene Moedt/ Foto Natura]

than 100 individuals. Other factors that affect reproductive rate include initial egg size, parental performance, predation, human disturbance, tick infestations, age and experience of the female, timing of laying, food availability, and weather. Older, experienced females do better, though their productivity declines after 12-14 years of age, and early or mid-season nests achieve the best success. Not surprisingly, prolonged rains chill chicks and impair the adults' feeding, while hurricanes and wind-driven waves and storm tides wash out nests and even whole colonies.

Terns are long-lived seabirds. Indeed, they outlive their rings, so true longevity estimates are lacking for most species. An Arctic Tern reached 34 years and a Sooty Tern 32, while Caspian, Sandwich, Great Crested, Common and Least Terns have all exceeded 20 years. Many other species have records of around 17 years, which are certainly lower than the true figure, although in most studies the life expectancy of a bird that has returned to breed is about 7-10 nesting seasons.

Movements

Most terns are migratory, although some tropical species are nomadic during the non-breeding season. Most of those breeding in the north temperate region winter in the tropics or the Southern Hemisphere, while the south temperate breeders have much more varied and less well understood movement patterns. This mirrors the migration of landbirds as well, presumably reflecting ancient climatic conditions. Species such as the Arctic Tern remain at their breeding grounds for the minimum time necessary to mate, nest, and fledge their young. At lower latitudes, species such as the Common Tern may be present for a month before nesting, and may stop off near their breeding grounds for several weeks before migrating. Some pelagic species, for example Grey Noddies, are present near their colonies throughout the year, whereas others, such as Sooty Terns, may be absent for several to many months. Much migration of large flocks occurs at night, although flocks can be seen moving in the early morning and late afternoon. The steady migration of Bridled Terns past Sri Lanka continues for many days, within a few hundred metres of the shore. In Ghana, radar revealed a much heavier autumn than spring passage, with up to 30,000 terns (of five species) present on a single day.

Several species show a distinct post-breeding dispersal to higher latitudes while the young are still partially dependent. This takes them to richer feeding areas, where they can learn feeding techniques prior to migration to the tropics.

Some species are long distance migrants, travelling from north temperate or Arctic breeding grounds to winter in the Southern Hemisphere. Others travel shorter distances. In general, many of the intermediate-sized terns breeding in temperate and Arctic regions migrate farther than the larger terns. The Arctic Tern has the longest transequatorial migration of any bird, travelling to the Antarctic from its Arctic breeding grounds. Arctic Terns from the eastern Canadian and European Arctic migrate through the eastern South Atlantic and then split, most continuing along the African coast, some passing through the mid-Atlantic and some crossing the Atlantic to move southwards off Brazil and the Argentine coast; the first group reach South Africa by October and then continue east-south-east ahead of trade winds to the edge of the pack ice, where they remain for 3-4 months. Other species, such as Nearctic populations of the Common and the Roseate, migrate from north temperate regions to the northern and central coasts of South America. Sooty Terns from the Dry Tortugas migrate east across the Atlantic and south down the coast of Africa, returning north in the West Atlantic. The movements of some species are less well known: the Aleutian Tern, for instance, leaves its breeding colonies in the North Pacific but its wintering areas are not known, although a few have been found in the Philippines.

Some tropical species, including some Sooty Tern populations, move great distances during the non-breeding period, but they move around the globe ahead of the trade winds in tropical regions, rather than in a north-south direction. Little is known of the migration of most Southern Hemisphere species.

Vagrancy occasionally occurs among terns. There are several records of Nearctic species in Europe, and a number of West Palearctic terns have made the reverse journey. Perhaps the most extraordinary record of all, however, is that of the Aleutian Tern which appeared in Britain in May 1979, far distant from its breeding range in the northern Pacific.

Relationship with Man

Many terns breed along coasts and inland waterways, and they have thus had a long history of interactions with man. Over much of this mutual history, terns have been exploited for food, fashion and information. Eggs, chicks and adults have been used for food, and feathers and whole birds have been utilized for capes, hats and other apparel. Since terns often feed over dense schools of fish forced to the surface by large, predatory fish, fishermen have long searched for these frenzied flocks, beneath which large bluefish, tuna or other food-fish can be caught.

The Sooty Tern is one of several pelagic species that do not carry prey in the bill. It returns to the colony with several fish or squid in the crop, and regurgitates them directly into the chick's bill. This enables it to transport a greater number of items and make far fewer trips each day to the feeding grounds, which are often far from the colony. It is interesting to note that, since the adult swallows fish head-first and regurgitates them tail-first, the chick swallows them tail-first; with soft-bodied squid, such details are likely to be less significant.

[*Sterna fuscata serrata*, Lord Howe Island, Australia. Photo: Jean-Paul Ferrero/ Ardea]

Throughout history, bird eggs have provided an easily acquired, high-protein, low-cost food source. Exploitation of tern eggs has been recorded for most species, and for most areas of the world. Even terns nesting on remote oceanic islands were exploited by early mariners, who regularly stopped at these islands to load up on eggs. Since the breeding season of many tropical terns, as well as other seabirds, is often prolonged and may extend over much of the year, eggs were readily available. When they were not, large chicks were present to be taken.

Even today, and despite legal restrictions, egging is a problem for many tern species, because colonies are often in places that are hard to monitor and eggs are often highly prized. In some places, tern eggs are sought as an aphrodisiac. Such qualities are attributed to Roseate and Sooty Tern eggs by people in the West Indies, who collect their eggs while those of more common species are ignored. Egging for hotels and restaurants persists in some European and South American countries. Managed egging of Sooty Terns in the Seychelles has been successful in maintaining a stable population, and has been proposed in Jamaica and elsewhere. Similar controls have been shown to be effective in parts of Europe.

For centuries, the feathers of birds have been used to decorate clothing and ceremonial paraphernalia. During the second half of the nineteenth century, however, terns were exploited even more heavily by the European millinery trade. White was a favourite colour for ladies' hats and capes, and terns provided an easy source of white feathers. Towards the end of the craze, entire wings and whole terns were used on hats in fashionable circles.

Recently, terns have been used as bioindicators of environmental contamination. Population size, reproductive success and the incidence of developmental defects have been monitored as indicators of potential exposure; behavioural and morphological abnormalities have been examined as indicators of toxins; and levels of organochlorines and heavy metals in eggs and dead birds have been used as indicators of environmental pollution. Thus, humans are currently exploiting terns as providers of early warnings of potential human health problems, as well as monitors of environmental quality.

Status and Conservation

Although terns have a worldwide distribution, most individual species have more restricted ranges, and several taxa are threatened, while for other very rare taxa information remains inadequate. Surprisingly, the Gull-billed Tern is the most cosmopolitan, occurring on all continents except Antarctica, although it is nowhere numerous. The Roseate Tern is nearly as widespread, although it barely breeds in South America. Several other species, such as Arctic, Caspian and Common Terns, have Holarctic ranges; Sooty and Bridled have pantropical ranges; and the Antarctic Tern is widespread in the Southern Ocean. Other terns are confined to relatively narrow breeding ranges: the Damara to southern Africa, the Black-fronted to New Zealand's South Island, Saunders's and the White-cheeked (*Sterna repressa*) to the northern Indian Ocean, and the Kerguelen to three archipelagos in the southern Indian Ocean.

The global population sizes of the various species of tern vary considerably, ranging from only a few thousand pairs of Fairy and Kerguelen Terns to several tens of millions of Sooty Terns. The Elegant and Damara Terns are near-threatened. The Californian and interior populations of the Least Tern number only a few hundred pairs, and the Easter Island race of the Grey Noddy is close to extinction, if not already extinct. The Roseate Tern is listed as endangered in North America and Europe, is threatened in the Caribbean, and is uncommon to common elsewhere.

Virtually nothing was known of the Chinese Crested Tern until 21 birds were collected on the Shantung coast in 1937. It was long considered extinct, none having been collected in the 60 years since then, but a few recent reliable sight records from wintering grounds indicate that small numbers survive somewhere. It is the only tern of which the breeding grounds have never yet been found.

The Kerguelen Tern probably has the smallest total population of any tern species: under 3000 pairs, almost all at Kerguelen Island, where it is threatened by cats. It avoids competition with the Antarctic Tern by breeding earlier and exploiting upland insects when the fish-eating Antarctic Tern is present. The Fairy Tern of Australasia may number no more than the Kerguelen Tern.

New Zealand's Black-fronted Tern also has a small global population, and hydro-electric projects proposed for some South Island rivers could dramatically alter its habitat, which is already being greatly reduced by proliferating lupins (*Lupinus*), which grow in profusion on the rocky and sandy islands in the braided rivers which are this tern's main breeding grounds. In southern Asia, the Black-bellied Tern is thought to number fewer than 10,000 individuals; it is threatened by habitat destruction and flooding of nests, and its eggs are also collected for food.

The populations of Peruvian and Damara Terns are difficult to determine, as these species nest solitarily or in very open colonies

of only 3-10 pairs on remote parts of beaches. Both are markedly uncommon, even where their beaches have not been highly developed. Throughout the world, tern populations have declined, and there is serious concern that several species might not survive. The Damara Tern was formerly considered endangered, but recent counts of 5000 birds provide some cause for optimism. More than 1000 km of Namibia's "Diamond Coast" is off-limits to the public and could afford protected habitat for this species. Its status there is inadequately known, however, and increasing mining developments in the area may jeopardize even this habitat.

The combination of egging, hunting and exploitation for feathers (see Relationship with Man) resulted in massive declines in most terns nesting along the coasts of North America and parts of Europe during the latter part of the nineteenth century, and many nesting populations were completely eliminated. It was when the protective laws for migratory birds were enacted in the twentieth century that tern populations began to recover. Their recovery, however, was dampened and halted in some regions because of habitat loss and competition with gulls.

During the present century, tern populations have suffered serious declines in many regions of the world because of competition with gulls. When human persecution of gulls ceased at the turn of the century, and when refuse became more available, gulls began to increase their populations and expand their ranges, often settling on traditional terneries, rendering them unsuitable for the terns when they arrived weeks later. Terns were forced to shift to sub-optimum nesting habitats. Gulls also prey directly on the eggs and chicks of terns. Since gulls normally arrive on the breeding colonies 2-3 months before the terns, and are up to four times larger depending on species, the terns are at a decided disadvantage. Although there is widespread agreement that gulls have had a direct impact upon tern populations, there are exceptions. In Germany, Little and Common Terns began to decline in the 1950's and 1960's, when gull populations were slowly increasing, but in the 1970's both species increased rapidly. Terns have been eliminated by gulls from many of their breeding colonies in parts of North America, Europe and Australia. Gull-control measures are required in many places before tern colonies can be re-established. This is a continuous problem, and in some areas the terns will need constant protection from the gulls if their colonies are to survive.

Terns often suffer heavy predation from predators introduced by man, or with populations that have increased because of human activities. Dogs, cats and rats introduced accidentally or deliberately are major predators, even on remote oceanic islands. Foxes and raccoons (*Procyon lotor*) were very rare on barrier beaches and coastal islands of the north-east USA, until man provided food for them to survive over the winter; they are now able to prey on the terns when they arrive. Humans have also introduced rabbits, goats and pigs on remote islands, resulting in serious habitat degradation. On a worldwide basis, cats are probably the most serious mammalian threat to island-nesting seabirds, including terns; they are both formidable predators and difficult to control or eradicate from islands. Avian predators include gulls, which take eggs, chicks and even adults; herons, which prey on chicks; and owls and raptors, which take adults.

Today, terns benefit from some human activities, for instance by foraging behind ploughs or boats or around fishing nets. However, otherwise they suffer from the impacts of man, such as overfishing, chemical pollution, human disturbance, and habitat loss and degradation of traditional nesting areas. The usurpation of their coastal nesting habitat by recreational, residential and commercial development was already recognized by conservationists in the 1950's and has continued despite conservation efforts. With beach stabilization and the control of mosquitos, coastal areas have been extensively developed, often reducing the habitat available to nesting terns. Both young and adults of coastal species often die from becoming entangled in fishing line and plastic items.

Terns have suffered at the hand of man as, in many parts of the world, overfishing has eliminated the fish for both terns and, eventually, the fishing industry itself. The northern isles of Britain, Orkney and Shetland, hold particularly high densities of breeding Arctic Terns, which feed almost exclusively on sandeels (*Ammodytes*). When sandeel stocks collapsed in the 1980's, virtually no tern chicks fledged in any Shetland colony during 1984-1990; breeding numbers fell from 31,000 pairs in 1980 to 8000 pairs in 1990. Although the local sandeel fishery may have caused the crisis, there was little scientific evidence for this, and the low recruitment of sandeels was possibly related to oceanographic factors. The fishery was closed in 1991, and sandeel recruitment in that year was excellent, for the first time since 1983. The once-largest Shetland colony had been reduced to 115 pairs in 1990, but in 1991 over 1000 pairs

Some studies have shown that the size of fish brought to chicks tends to increase as the chicks grow. As this photograph demonstrates, however, this may reflect prey availability rather than selection; this very young Caspian Tern would have an extremely hard time dealing with a fish of this size! All terns run the risk of food being pirated during the food transfer, and especially while chicks are trying to swallow particularly large fish. When taking food, the chick jerks its body and head until the fish's head is in its gullet, then jerks its head again until the food is swallowed; if it stops to rest, its fish may be stolen.

[*Hydroprogne caspia*. Photo: Geoff Moon/FLPA]

Some tree-nesting species, such as the Black Noddy, build a nest of twigs and leaves cemented together with excreta; nest-site selection therefore takes place earlier than in most other species, which make a small nest or none at all. On some islands Black Noddies nest in Pisonia *trees, as here, and the young may become trapped by the sticky seeds, which can form dense mats in some years. It is most unusual to see two Black Noddy chicks in one nest, as this species normally lays only one egg. Noddies appear not to be able to recognize their own chicks; one of these two has presumably dropped out of another nest.*

[*Anous minutus minutus*, Heron Island, Great Barrier Reef, Australia. Photo: Gary Bell/ Planet Earth]

nested, many of which had been ringed there as chicks in the period 1979-1983; they reared 0·67 chicks per pair. Since then, however, breeding numbers have not recovered further, probably as a consequence of the long period of breeding failure.

Tern populations can also be seriously affected by pollutants. Forster's Terns nesting in Green Bay, Michigan, have suffered low reproductive success over a number of years; hatching success of artificially incubated eggs was 52% that of nearby uncontaminated colonies. No tern pairs in the Green Bay colonies fledged young, compared with a 55% fledging rate for colonies inland from the polluted bay. Egg-exchange experiments confirmed that both intrinsic and extrinsic factors contributed to the poor hatching success. Embryos from the Green Bay colonies weighed less, had increased liver weights and had shorter femurs compared with the inland colonies, and some had deformities. These abnormalities were similar to those reported for other fish-eating colonial birds from the Great Lakes, and were directly attributed to high levels and complex mixtures of lipophilic environmental contaminants.

The simultaneous decline of the Roseate Tern in Europe and North America is at least partially attributable to harvesting on the wintering grounds in West Africa and northern South America, where large numbers of birds are taken. A metapopulation study of the population of the north-eastern USA showed low annual adult survival of only 75%, compared with values greater than 85% for most other seabirds studied.

Although many tern populations are declining, some are increasing and expanding their ranges, while others are subject to great fluctuations. The populations of the Sandwich Tern in northern Europe fluctuate widely, but in eastern North America the species has been on the increase in recent decades, and its "Cayenne" race is extending northwards in the Caribbean. Forster's Tern has increased in many parts of the Great Lakes, while other species have declined in the same area. Arctic Tern populations in Scandinavia have increased, probably owing to the elimination of egging. There are many accounts in the literature of one or a few pairs of terns pioneering in new locations since 1970.

Declining species benefit from conservation management. Many tern populations already nest on protected reserves, but other important sites need protection. Acquiring private land can be a major first step, but habitats have to be secured and managed. Formerly, terns had abundant choices once a traditional site became unsuitable. Now they may have nowhere to turn to.

Stabilization of sandy islands, creation of artificial nesting platforms, removal of vegetation, and maintenance of water levels in marshes can all play major parts in habitat management. Removal of predators, particularly feral cats, and elimination of rats are time-consuming but important processes. Cats, if their current petrel prey became scarce, could quickly eradicate the Kerguelen Tern population on that island.

There are many reports on the effects of pollutants, but the magnitude of any impact on tern populations needs to be studied. Efforts must be made to limit pollution discharges, particularly the release of oil in intracoastal waterways. A combination of habitat protection, predator elimination and the use of decoys can successfully attract terns to suitable sites, and allow the re-establishment of thriving colonies. Terneries must then be signposted, fenced, or even wardened to exclude human activities which might jeopardize tern reproduction. In tropical regions, the conservation efforts are at an earlier stage, for egging is still widespread, even where terns are ostensibly protected by law.

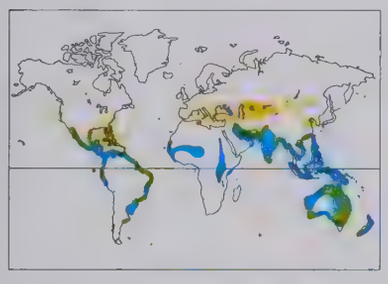
PLATE 54

inches 6
cm 16



Genus *GELOCHELIDON* C. L. Brehm, 1830

1. Gull-billed Tern

Gelochelidon nilotica

French: Sterne hansel **German**: Lachseeschwalbe **Spanish**: Pagaza Piconegra

Taxonomy. *Sterna nilotica* Gmelin, 1789, Egypt.
Along with *Hydroprogne* and *Thalasseus*, genus often merged with *Sterna*; behaviour intermediate between typical terns and crested terns, and unique combination of characters supports separate generic treatment. Listed as *G. anglica* in many older works. Proposed race *affinis* for birds of E Asia and SE China is not separable. Six subspecies recognized.
Subspecies and Distribution.
G. n. nilotica (Gmelin, 1789) - Europe S to Mauritania and Tunisia, and E through Middle East, Kazakhstan and Indian Subcontinent to NW China; winters from tropical Africa through Persian Gulf to India.
G. n. addenda Mathews, 1912 - Transbaikalia, Manchuria and E China (Fuzhou to Hainan); winters mainly SE Asia.
G. n. macrotarsa (Gould, 1837) - Australia.
G. n. aranea (Wilson, 1814) - New Jersey (rarely New York) S to Texas, Cuba, Bahamas and Puerto Rico, and sparsely along Mexican coast to Yucatán; winters along Central American coasts and S to Brazil and Peru.
G. n. vanrossemi Bancroft, 1929 - California (coastal plain and Salton Sea) to N Baja California and Sinaloa (and probably S to Gulf of Tehuantepec), with isolated breeding recorded in Alaska (Copper R Delta); winters S to Ecuador.
G. n. groenvoldi Mathews, 1912 - coast and river valleys from French Guiana (Cayenne) to NE Argentina (Buenos Aires); Ecuador and N Peru breeders may be this race or *vanrossemi*, or an undescribed race.

Descriptive notes. 33-43 cm; 130-300 g (*nilotica* 190-290 g, *aranea* 160-185 g); wingspan 85-103 cm. Unique heavy-billed, long-legged tern with slightly forked tail, broad wings and very pale body; all black bill has sharp gonydeal angle, but no terminal hook, resembling that of small gull; eye dark brown; crown and nape black, upperparts including rump pale grey, primaries slightly darker but wingtips whitish to pale grey; tail and underparts white. Non-breeding adult nearly pure white with some dark streaking on hindcrown, and dark patch behind eye. Juvenile has scapulars and upperwing-coverts variably splotched with brown; head white with fine dark speckling. Races differ mainly in size, especially of bill, and also in colour tone of upperparts; *macrotarsa* is largest race, especially in bill and feet.
Habitat. Breeds on barrier beaches and dunes, salt-marshes, salt-works, man-made islands, and rivers and freshwater lagoons; far more along coastal plains than in continental interiors, but also breeds on hypersaline lakes; race *aranea* strictly coastal. Often feeds in large numbers on emerging insects over lakes, fields and grassland, and in Azerbaijan even over semi-desert; migrants typically feed over salt-ponds, coastal lagoons and mudflats, as well as marshes and wet fields. Winters on estuaries, lakes and salt-pans.
Food and Feeding. Opportunistic: more insectivorous than most other terns, prey including mainly grasshoppers, dragonflies, moths and grubs; also takes spiders, earthworms, small reptiles and frogs, small fish (mainly 6-9 cm) and aquatic invertebrates; rarely voles and small birds. More varied diet and larger items in N Europe than in S Europe. In Italy, 67% of food items were reptiles in one study, mostly insects in another. In Russian steppes, 80% Orthoptera. Hawks for insects over estuaries, mudflats, coastal lagoons and agricultural fields and pastures. Flies slowly and then darts swiftly down to seize prey item from surface of ground, water or vegetation; does not feed by surface-dipping, and plunge-dives only exceptionally. Occasionally pirates food from other terns. In Italy, most birds foraged within 2 km of colony, occasionally up to 11 km.
Breeding. Lays May-Jun in North America and Europe, Apr-May in India, Oct-Dec in Australia. Loosely to densely colonial, usually 5-50 pairs, but up to 1000 pairs; often 1-2 pairs nest in colonies of other terns or Common Black-headed Gulls (*Larus ridibundus*). Low to moderate colony site tenacity, e.g. turnover 0·38 in Italy; larger clutches and higher productivity in larger colonies; coloniality deters gull predation. Prefers vegetated nest-sites in Italy, but often nests on barren beaches in E USA; nests on sand, shell bars, dry mud, dykes, seawrack, floating vegetation, waterfowl nests; prefers elevated ridges or objects, and recorded nesting on roofs. Nearest-neighbour distance ranges from 20 m in small colonies to 0·3 m in large colonies. 2-3 eggs (1-5), with average 2·5 in Denmark and North Carolina, but 2·2 in S California; incubation 22-23 days; chick white, usually unspotted; hatching weight 24 g; fledging c. 28-30 days; parents attend young for 3 months. Productivity often low in USA. Returns to colony at 4 years old, but first breeding at 5 years. Recorded longevity of 15 years 9 months.
Movements. European birds disperse in all directions after breeding, then migrate across Spain, Italy and N Africa to W Africa, Rift Valley and coastal E Africa; others of nominate race winter E to India, and occasionally Indonesia, while E Asian breeders winter mostly in SE Asia. E North American birds migrate to SE USA and Gulf of Mexico; some cross to Pacific; some winter along Costa Rican coast, others reach even Brazil and Peru. Birds of W North America winter from W Mexico to Ecuador; vagrant to West Indies. In E Australia, species nomadic; may wander to remote lakes in interior after rains, and remain to breed.
Status and Conservation. Not globally threatened. Nowhere abundant, and considerable decline noted in recent years in Europe. World population estimated at up to 55,000 pairs centred mainly in CIS, which holds up to 40,000 pairs, including 2000 on L Alakol'. Estimated 6800-16,000 pairs in Europe, with 1800-5000 pairs in Russia, 1869 pairs in Spain (in 1989), and perhaps 2000-7000 pairs in Turkey; also 3000 pairs in E North America, and 2000+ pairs in W Africa. As with most terns, numbers seriously depleted in late 19th century by millinery trade, with slow recovery in 20th century, until confronted with major problems of habitat loss, human disturbance and pesticides; many populations have declined since 1960's. In E USA, c. 2700 pairs in 83 colonies in 1977, but only 1500 pairs in 1984. Main causes of decline in Europe are deterioration and loss of habitat, caused by: wetland drainage; agricultural intensification; pesticides and other chemicals, causing death of prey species or of birds themselves; changing water levels, causing flooding or facilitating access to colonies for predators.

Genus *HYDROPROGNE* Kaup, 1829

2. Caspian Tern

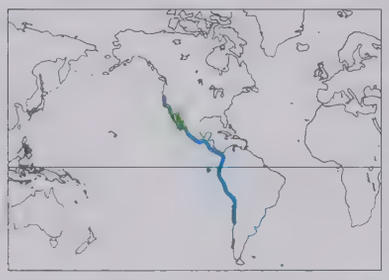
Hydroprogne caspia

French: Sterne caspienne **German**: Raubseeschwalbe **Spanish**: Pagaza Piquirroja

Taxonomy. *Sterna caspia* Pallas, 1770, Caspian Sea.
Along with *Gelochelidon* and *Thalasseus*, genus often merged with *Sterna*, based primarily on ethological evidence; differs from all other terns, however, in massive, heavy bill. Species name often given as *H. tschegrava*, particularly in recent Russian works, both names dating from same year; to avoid further confusion, name *tschegrava* officially suppressed in 1970. Australian and New Zealand birds sometimes separated as race *strenua*, but characters matched by many individuals of other populations. Monotypic.
Distribution. North America, N Europe (Baltic), Africa, Madagascar, C & S Asia, Australia (coastal and sparsely inland), New Zealand; everywhere very local. Probably bred in British Columbia (1984); recent fledglings observed in delta of R Copper suggests breeding in Alaska. Disperses more widely in winter.

Descriptive notes. 48-56 cm; 574-782 g; wingspan 127-140 cm. Largest tern; large, stout blood red bill with variable black tip, and slightly forked tail; also distinguished by black undersurface of primaries, conspicuous in flight; eye dark brown, legs black. Non-breeding adult has forehead and crown whitish with dark spotting. Confusable only with *Thalasseus maximus* and *T. bergii*, which have orange or yellowish bill and paler under primaries, but is much more gull-like than either and never becomes as white-headed as is *T. maximus* for most of year. Juvenile grey above with brown bars, strongest on scapulars and inner secondaries; crown mainly white; tail and primaries dark grey; bill red-orange with blackish tip.
Habitat. Locally along coasts, as well as on large inland lakes and reservoirs, breeding on sand, shell or rocky islands, rarely on salt-marsh (New Jersey, USA). Feeds at freshwater lakes, inland seas, and coastal estuaries; rarely pelagic. Winter roosts at large lakes and estuaries on sandbars, mudflats, shell banks.
Food and Feeding. Mainly small to medium-sized fish; occasionally eggs and young of other birds, and carrion. Takes larger fish (usually over 9 cm and up to 25 cm) than smaller terns with which it associates. In Scandinavia, main prey roach (*Rutilus rutilus*) and herring (*Clupea harengus*). In Ukraine, cyprinoids comprise 80% of diet. In USA, at L Michigan main prey alewife (*Alosa pseudoharengus*) and smelt (*Osmerus mordax*); in Elkorn Slough, California, birds fed mainly on northern anchovy (*Engraulis mordax*, 49%), shiner perch (*Cymatogaster aggregata*, 29%), topsmelt (*Atherinops affinis*, 19%), and Pacific staghorn sculpin (*Leptocottus armatus*, 3%); in Washington, northern anchovy ranged from 0% in 1975 to 44% in 1976. Often feeds in loose flocks, but occasionally exhibits feeding territoriality. Hovers and plunge-dives, and occasionally uses surface-dipping; also pirates food from other terns and gulls. Feeds up to 60 km from colony.
Breeding. Apr-Jun in N Hemisphere, Sept-Dec in S Hemisphere, but nearly year round in N Australia. Densely colonial to solitary: in Europe, most breed as single pairs in gull or tern colonies; solitary pairs exclude conspecifics from the colony. 25% of pairs remained mated in second year of a study. Colony site tenacity high if previous breeding attempt successful; some colonies have been occupied for 100 years. Very sensitive to disturbance early in cycle and entire colony will desert. Nest a depression in sand, gravel, shell, or even ground vegetation; in colonies, nests 0·7-4 m apart. Clutch 2-3 eggs, fewer at lower latitudes: averages more than 2·5 in Great Lakes (USA) and Finland, 2·5 in Washington (USA) and 1·9 in Texas (USA); larger clutches (4+ eggs) may be due to female-female pairing in some colonies. Incubation 26-28 days (earlier reports of 20-21 days erroneous); chicks dimorphic, pale creamy whitish with faint or no spots, white throat, yellowish skin, and orange feet, or greyish brown with dark spots, sooty throat, dark skin, and olive feet (a few intermediate); hatching weight 70 g; adults rely at least partly on down colour for chick recognition; chicks remain in nest 3 days; fledging c. 35-45 days; prolonged parental care continues, at least occasionally, even in winter quarters. Productivity 1·5 chicks/

On following pages: 3. Elegant Tern (*Thalasseus elegans*); 4. Lesser Crested Tern (*Thalasseus bengalensis*); 5. Sandwich Tern (*Thalasseus sandvicensis*); 6. Chinese Crested Tern (*Thalasseus bernsteini*); 7. Royal Tern (*Thalasseus maximus*); 8. Greater Crested Tern (*Thalasseus bergii*); 9. River Tern (*Sterna aurantia*).



pair in Finland. Some 2-year-old birds return to colonies and may breed, but most wait until 3 or 4 years. Annual adult mortality 9-15% (Finland), 11% (California). Longevity of 26+ years recorded.
Movements. North American and European birds show brief post-breeding dispersal, then migrate slowly S. Great Lakes birds move S and E to Gulf and Atlantic coast to winter in SE USA and Caribbean, rarely reaching Panama and Trinidad; those from W USA winter from C California to Mexico. Baltic birds pass through C Mediterranean and E Europe en route to tropical W Africa (particularly Mali) and C Africa (approximately to equator), and Middle East. In Australia, juveniles disperse widely; Tasmanian birds winter in New South Wales; Queensland birds may disperse S as well as N. Juveniles wintering S move further than adults; most 2nd-years remain in wintering area in spring. Spring migration usually rapid.
Status and Conservation. Not globally threatened. Many vulnerable populations, and recent decline in some areas. World population probably c. 50,000 pairs: 15,000 in CIS, 12,000 in North America, 3000 in Europe, c. 5000 in W Africa, and 500 in S Africa; fewer than 5000 in New Zealand, but many thousands in Australia. Californian population grew by 70% from 1960 to 1980, reaching 6000 pairs. Declining in Baltic, and fewer than 500 pairs in Sweden in 1994. Nearly eliminated from most E North American and C European colonies in late 19th century, with gradual recovery in mid-20th century. Listed as threatened in Canada, where some colonies subject to vandalism. In E North America, rapid plant succession on dredge-spoil islands limits habitat. Reliance on relatively large fish increases exposure to bioaccumulated contaminants such as chlorinated hydrocarbons and methyl mercury. Some local evidence of organochlorines causing eggshell thinning and hatching failure.

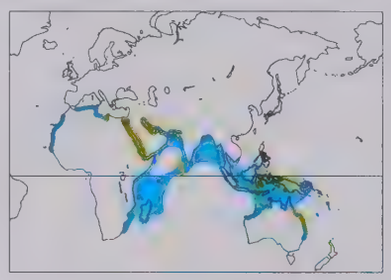
Genus *THALASSEUS* Boie, 1822

3. Elegant Tern
Thalasseus elegans

French: Sterne élégante **German**: Schmuckseeschwalbe **Spanish**: Charrán Elegante

Taxonomy. *Sterna elegans* Gambel, 1849, Mazatlan, Sinaloa, Mexico.
Genus often merged with *Sterna*, but the six species here placed within *Thalasseus* do share certain common features of morphology which set them apart from other terns. Forms superspecies with *T. bengalensis* and *T. sandvicensis*, and perhaps *T. bernsteini*, and subspecific status has even been suggested. Monotypic.
Distribution. Pacific coast of North America, with very restricted breeding range from S California to C Baja California and from Gulf of California to Nayarit.



Descriptive notes. 39-43 cm; 217-300 g (breeding), 186-246 g (winter, Peru); wingspan 76-81 cm. Typical crested tern with black cap and long crest, white body, and grey mantle and wings; underparts white, often suffused with rosy; bill long and very slender, varying from yellow-orange to bright orange-red; ratio of bill length to depth greater than 5:1; legs and feet black, but 10% have orange legs and feet. Crest longer and usually more extensively black than in *T. maximus*. Differs from *T. bengalensis* in having rump and tail white, rather than pale grey. Non-breeding adult has white forehead and crown. Juvenile strongly mottled dark above. Immatures have darker grey secondaries, upperwing-coverts and tail feathers, and variable soft-part coloration; bill usually yellow.
Habitat. Sandy beaches and low-lying islands along coast and estuaries. Migrants feed in harbours, estuaries, salt-ponds and lagoons, resting in tight flocks on mudflats and sandbars.
Food and Feeding. Small fish. Preferred food is northern anchovy (*Engraulis mordax*). Flies at height of 1-3 m, then plunge-dives. Non-breeders feed in lagoons and bays, avoiding rough waters. In winter in Peru, plunge-dives beyond surf, mainly for small fish, and does not feed with other terns and gulls on abundant mole crabs (*Eremita analoga*) on wave-washed beach. In Peru, present species is favoured victim of piratical attacks by Arctic Skuas (*Stercorarius parasiticus*).
Breeding. Relatively few studies. Laying Apr-May. Dense nesting aggregations with hexagonal packing of nests (9-10 nests/m²), forming highly synchronous subcolonies. 1 egg (less than 2% of nests have 2 eggs); adults recognize own eggs; incubation c. 25 days; fledging 30-35 days; prolonged parental care continues until Nov. Colonies suffer predation by Heermann's (*Larus heermanni*), Western (*L. occidentalis*) and Yellow-footed Gulls (*L. livens*).
Movements. Post-breeding dispersal northward to N California and rarely to British Columbia. Uncommon migrant off Pacific coast of Costa Rica. Winters on Pacific coast from Guatemala to C Chile, mostly in Peru and N Chile. Accidental in Texas. Odd records from Netherlands, Ireland, Spain and France (including hybridization with *T. sandvicensis*), but provenance of such birds in question, as species virtually unrecorded anywhere in North America away from Pacific coast; probably attributable to escapes from shipments of exotic seabirds from wintering grounds in W South America.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Global population probably 30,000-50,000 pairs. Much of population vulnerable. Sometimes 90% of entire population nests on Isla Rasa (Gulf of California), where there have been drastic changes in numbers. First documented flocks in USA were in 1950's, and first nesting in 1970's. About 800 pairs nest in San Diego Bay (California). Colony at Bolsa Chica (California), where first nested only in 1987, has grown to 4000 pairs. Several former colonies in Mexico have been abandoned. Nearly eliminated from Isla Rasa by eggers, until the island was declared a sanctuary in 1964; estimated population there was 80,000 in early 1980's, but only 22,500 a decade later. Human disturbance from ecotourism is a threat.

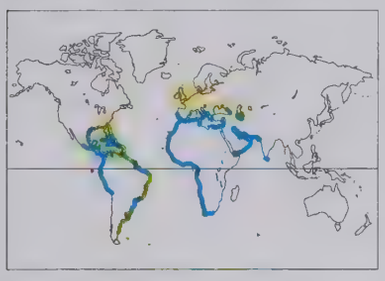
4. Lesser Crested Tern
Thalasseus bengalensis

French: Sterne voyageuse **German**: Rüppellseeschwalbe **Spanish**: Charrán Bengalí
Other common names: Crested Tern

Taxonomy. *Sterna bengalensis* Lesson, 1831, coasts of India.
Genus often merged with *Sterna*. Forms superspecies with *T. elegans* and *T. sandvicensis*, and perhaps *T. bernsteini*, and subspecific status has even been suggested. Often treated as monotypic, but described races based on subtle variation in plumage tone of upperparts and size: much overlap and intergradation, however, as well as intermediate populations, and distributions of races are confused; racial divisions require revision. Mediterranean and Red Sea birds sometimes classified together as race *par*; *emigrata* may be synonymous with *torresii*, although biogeographically allogical. Three subspecies normally recognized.
Subspecies and Distribution.
T. b. emigrata (Neumann, 1934) - Libya; most winter off W African coast.
T. b. bengalensis (Lesson, 1831) - Red Sea, and presumed to be this race in Pakistan, Laccadives and Maldives; winters S to S Africa and Sri Lanka.
T. b. torresii Gould, 1843 - Persian Gulf, and from Sulawesi to New Guinea and N Australia; in winter extends into N Indian and SW Pacific Oceans.



Descriptive notes. 35-43 cm; 185-242 g; wingspan 88-105 cm. Cap and crest black; upperparts uniform grey; bill orange to orange-yellow with yellow distal area, and slight droop towards tip; legs and feet black with yellow webs; iris brown. Underparts white, apparently less often tinged with pink than in *T. elegans* or *T. sandvicensis*; similar in size and appearance to *T. sandvicensis*, but bill colour differs; resembles *T. bergii*, but smaller, with proportionately longer, slimmer, orange (not dull yellow) bill; differs from all similar species in having rump and tail grey, not white. Non-breeding adult has white on forehead and crown and yellower bill. Juvenile paler than that of *T. bergii*, like *T. sandvicensis* but less heavily spotted and with darker flight-feathers; dusky grey band across upperwing-coverts. Conflicting evidence as regards racial variation, but most *torresii* from Australia are darker above than nominate; Mediterranean race *emigrata* larger and very slightly paler, said to be virtually identical to some *torresii*; many birds breeding in N Indian Ocean from Red Sea to Pakistan intermediate between these and nominate race.
Habitat. Tropical and subtropical coasts. Often associates with *T. bergii*, but tends to be more pelagic in Kenya and India. Breeds on low-lying sandy and coral islands and coral flats. Forages in surf and ranges offshore.
Food and Feeding. Mainly fish and shrimps. Feeds mostly on herrings (Clupeidae) in Sri Lanka, extensively on prawns in Pakistan. Quarters c. 5 m above water, turning, hovering and plunge-diving, often submerging; also surface-dips. Often feeds in large mixed tern flocks. Suffers heavy piracy from Silver Gulls (*Larus novaehollandiae*) on Great Barrier Reef, Australia, with loss of up to 23% of fish.
Breeding. May-Jun in Persian Gulf; Jul-Aug in Libya; Aug in Somalia; in Australia, breeds Sept-Dec in E, Mar-Jun in N and both seasons in W. Forms large, dense colonies (up to 20,000 pairs) on offshore islands, sandbanks and coral cays; shifts sites frequently. Often nests with *Sterna dougallii* or *T. bergii*; vagrants in Europe have produced hybrid young with *T. sandvicensis*. Average density 2·76 nests/m², but in high-density areas nests touch and may reach 9-10/m². Makes shallow unlined scrape in sand or shells, usually selecting ridges or bare areas surrounded by vegetation. 1 egg, rarely 2; incubation 21-26 days, occasionally 30 days; downy chick very pale to almost white above, with black spots on crown, back and wings forming fine lines, pure white below, with bill olive-yellow or black; led from nest at 2-4 days, and fed outside colony; from day 7 chicks of mixed ages form crèche, protected by adults; fledging 30-35 days; parental care to age of 5 months. Productivity not studied. Age of first breeding presumably 2 years.
Movements. Inadequately known owing to lack of ringing studies. Migratory in Mediterranean, with post-breeding movement to Morocco and Senegambia, but only partly migratory in most of range. Middle East birds pass E coast of Africa to Natal. N Indian Ocean populations partly migratory. Vagrant inland.
Status and Conservation. Not globally threatened. World population c. 225,000 pairs, more than half in Australia; c. 10,000 pairs in S Pacific; 8000 in Indonesia; 10,000 in E Africa; 50,000-60,000 in Middle East, with 24,500 pairs found on islands off Abu Dhabi in 1994, also c. 24,250 pairs off Saudi Arabia in early 1990's, and many 1000's in Iran; 10,000 in N Africa. Non-breeders common along coasts of S Asia, from Persian Gulf and both coasts of India to Indonesia. The commonest tern of Karachi.

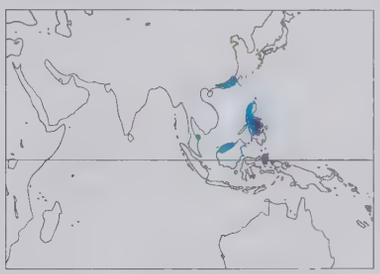
5. Sandwich Tern

Thalasseus sandvicensis

French: Sterne caugek **German**: Brandseeschwalbe **Spanish**: Charrán Patinegro
Other common names: Yellow-nibbed Tern; Cabot's Tern (*acuflavidus*); Cayenne Tern (*eurygnatha*)

Taxonomy. *Sterna Sandvicensis* Latham, 1787, Sandwich, Kent, England.
Genus often merged with *Sterna*. Forms superspecies with *T. elegans* and *T. bengalensis*, and perhaps also *T. bernsteini*, and it has been suggested that all may even be conspecific. Form *eurygnatha*, Cayenne Tern, generally considered separate species until work in S Caribbean showed it to be race or possibly morph of *T. sandvicensis*, and that all but northernmost New World populations have at least small percentage of "Cayenne"-type birds. Races *acuflavidus* and *eurygnatha* interbreed freely in S Caribbean, and mixed pairs occur also in Patagonia and Puerto Rico; possibility of assortative mating deserves further study. In Curaçao typical *acuflavidus* make up 20% of population, while in French Guiana they comprise less than 1%. Three subspecies currently recognized.
Subspecies and Distribution.
T. s. sandvicensis (Latham, 1787) - Europe E to Caspian Sea; winters from Caspian, Black and Mediterranean Seas to coasts of W & S Africa, and from S Red Sea to NW India and Sri Lanka.
T. s. acuflavidus (Cabot, 1848) - E North America (Virginia locally to Campeche Bank and Belize), and through Antilles to S Caribbean; winters from Caribbean S to S Peru and Uruguay.
T. s. eurygnatha (Saunders, 1876) - highly local breeder in Caribbean, off Venezuela and French Guiana (Cayenne), and from E Brazil to S Argentina (Buenos Aires, and Patagonia from Chubut to Santa Cruz).



Descriptive notes. 36-46 cm; 130-311 g (*sandvicensis* 130-285 g; *acuflavidus* mostly 175-202 g; *eurygnatha* 170-210 g in Caribbean, 250-300 g in Uruguay); wingspan 86-105 cm. Medium-sized pale tern with black cap and crest, long slender bill, long pointed wings and moderately long, forked tail; back and upperwings pale ash-grey; rump and tail white; underparts white, sometimes tinged with pink; primaries with white inner webs and silvery outer webs; bill varies from black with yellow tip (Europe and North America) to mainly or wholly yellow (South America); legs black, occasionally yellow. Similar in size to *Gelochelidon nilotica*, but has more slender bill and distinctive calls; usually differs from similar *Thalasseus* species in having dark bill. Non-breeding adult has white forehead and forecrown. Juvenile spotted dark above, with dark tip to tail. Races differ only slightly: *acuflavidus* slightly smaller, with outer tips of outer primaries grey rather than white; *eurygnatha* is mainly yellow-billed, but often with dark bill base; legs sometimes partly yellow, rarely all yellow.
Habitat. Strictly coastal and mainly a warm-water species. Favoured breeding sites are low-lying, and subject to inundation, wind-blown sand, erosion and human intrusion: prefers open, unvegetated sandy, muddy or gravelly or bare coral substrates, nesting on highest open area available; late breeders forced to nest closer to high tide line. Outside breeding season frequents sandy or rocky beach fronts, mangrove flats, estuaries and harbours. At Curaçao feeds mainly along seashore, sporadically in bays. Feeds in inlets over water 1·5-2 m deep and at sea, very rarely over fresh water.
Food and Feeding. Almost entirely fish, mostly 9-15 cm long, particularly menhaden (*Brevoortia*) and anchovies (*Anchoviella*) in USA, and sardines (*Sardinella*) in W Africa; flying-fish in Caribbean; occasionally small shrimps. Also swoops to pick up marine worms from mudflats, and takes shorebird chicks, including Pied Avocets (*Recurvirostra avosetta*) in E Europe. Plunge-dives for small fish, from greater heights than *Sterna hirundo*, up to 10 m. Feeds over fishing nets; scavenges over sea-lions and sometimes feeds over porpoise pods. May fish with *T. bengalensis*. Occasional intraspecific kleptoparasitism. In Italy, most forage 10-15 km from colony; up to 70 km in Scotland. May defend feeding territories along shore.
Breeding. May-Jun in Europe, mid-May in Curaçao, Jun in C Brazil, Dec in Argentina. Colonies rarely monospecific; usually nests next to other terns or Common Black-headed Gulls (*Larus ridibundus*) in Europe, or with *T. maximus* in Americas. Late-arriving terns displace *L. ridibundus* from centre of colony. Forms dense colonies: eggs sometimes only 20 cm apart; sometimes only 2 nest/m², but usually 5-7 (maximum 9). In Europe colonies contain up to 4000 pairs, mean 853, but one Dutch colony reached 35,000 pairs prior to 1960; 20,000 pairs in a Louisiana colony in 1970's; 1300 nests, mostly *eurygnatha*, in Curaçao in 1958. At some sites forms synchronous subcolonies of 5-25 pairs, but larger groups more synchronous than small ones. Frequent changes in colony site, particularly if predators become established early in breeding cycle, but tolerant of disturbance after egg-laying; prefers nesting far from upright vegetation, and abandons colonies when vegetation encroaches. Nest a shallow scrape rimmed with excreta. 1-2 eggs (1-3), with average 1·66; larger clutches in larger colonies and for older birds (5-year-olds average 1·81, 3-year-olds 1·33), with highest mean 2·07 in large Scandinavian colonies; 1·7 in Argentina. Incubation 21-29 days, average 25 days; chick whitish to buff, grey or brown, with few or heavy black speckles; hatching weight 22-24 g; in some colonies, young form crèche at 1-2 weeks; fledging 28-35 days; prolonged parental care into 1st winter. Productivity very variable, c. 0·6/pair, higher in larger colonies. Average hatching success 47-81%, lower in high-density areas, and for late eggs (0-60%). Fledging success usually 80-90%. Older early breeders more successful. Some birds breed at age 3, most not until 4. Oldest recorded bird 23 years 7 months.
Movements. Post-breeding movement both N and S to favourable feeding grounds, until S migration begins in mid-Sept. European birds move S along W coast of Africa, to winter mostly in tropics, a few remaining in W Europe; up to 35,000 off Mauritania in Dec. Adults move further S than young, the latter spending their 2nd year in Africa. Many Black Sea birds winter in the Mediterranean or Black Seas; rarely reach W Africa. Caspian Sea birds winter in the N Indian Ocean from S Red Sea to Pakistan, including Persian Gulf, but some remain in the Caspian and a few reach S India and Sri Lanka; irregular winter visitor E Africa (Kenya, Tanzania). North American birds move S through Caribbean and along both coasts of Central America to South America; some linger in SE USA and Caribbean, others reach Uruguay and W South America; sometimes numerous on C coast of Peru. Race *eurygnatha* winters in S Caribbean and along Atlantic coast of South America to Argentina; some post-breeding wandering in Gulf Stream N to North Carolina; few sightings from Colombia, including one on Pacific Coast. In Uruguay, *eurygnatha* is uncommon along coast in breeding season, while typical *acuflavidus* appears in winter from North America.
Status and Conservation. Not globally threatened. World population at least 100,000 pairs, including c. 45,000 in E USA and 40,000 in Europe; but estimate of c. 40,000 pairs at Caspian Sea alone in 1985, and of 75,000-80,000 for whole of former USSR. Total *eurygnatha* population may be under 20,000 pairs. Significant decline in NW Europe (Wadden Sea) attributed in part to organochlorines, and in W Europe due to human disturbance on breeding grounds and human predation on wintering grounds. Fluctuating population levels obscure trends. UK populations rebounded in first half of 20th century to 15,000+ pairs. Netherlands population increased to 40,000 pairs in 1950's, declined to 12,000 in 1961 and only 650 in 1965, apparently due to pesticides; then increased to 6000 in late 1970's. First bred in Sweden in 1911, and in Norway in 1974. In USA, has increased slightly during present century in Middle Atlantic States. Race *acuflavidus* extending SE since the 1970's, and now meets and interbreeds with *eurygnatha*; latter extending N, first noted in Curaçao in 1952, Virgin Is in 1970's, and Culebra (Puerto Rico) in 1986. Few colony sites known from E South America. First discovered breeding in Argentina in 1964. Colonies vulnerable to human disturbance or heavy predation, particularly early in season, and birds sometimes abandon eggs en masse. Suffers heavy predation from Laughing Gulls (*Larus atricilla*) in Curaçao. Egging a serious threat throughout tropics, and capture of wintering birds in W Africa potentially significant. Responds favourably to habitat management, such as clearing of vegetation and site protection, and in Europe and Caribbean readily attracted to suitable nesting habitat by use of decoys.

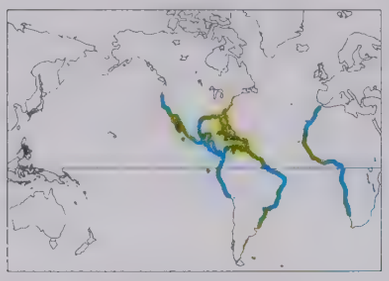
6. Chinese Crested Tern

Thalasseus bernsteini

French: Sterne d'Orient **German**: Bernsteinseeschwalbe **Spanish**: Charrán Chino

Taxonomy. *Sterna bernsteini*, Schlegel, 1863, China.
Genus often merged with *Sterna*. Species closely related to *T. bengalensis*; may belong to *T. sandvicensis* superspecies. Formerly known as *T. zimmermanni*. Monotypic.
Distribution. Breeding areas unknown, possibly on coast of N China in Shandong: on islands near Qingdao and on islet of Mukuantao, or at delta of Huang Ho (Yellow R). Winter records from E China S to Indonesia.



Descriptive notes. 42 cm. Similar to *T. bengalensis*, but bill stouter, with more pronounced gonydeal angle, orange-yellow with broad black tip; back paler grey.
Habitat. Presumably coastal estuaries.
Food and Feeding. Unknown. Presumably fish.
Breeding. Presumably May-Jul, but breeding sites have never been found. Nothing known.
Movements. Appears to migrate to tropics, where recorded from E China (Fujian, Guangdong), Philippines, NW Borneo (Sarawak), S Thailand and Halmahera.
Status and Conservation. CRITICALLY ENDANGERED. Virtually unknown, and possibly even extinct, but several recent sight records suggest species may survive. Last collected at Tsangkow near Qingdao (Tsingtao), and on Mukuantao islet off Shandong coast, where 21 specimens taken in 1937, some in breeding condition; long feared extinct. Most recent record is of 10 birds near Libong, S Thailand, in Jul 1980, but 3 terns probably of this species reported in Huang Ho Delta in Sept 1991. May be overlooked among flocks of *T. bergii*. Survey work urgently required.
Bibliography. Andrew, P. (1992), Collar & Andrew (1988), Collar *et al.* (1994), Dickinson & Eck (1984), Dickinson *et al.* (1991), Étchécopar & Hüe (1978), King (1978/79), LaTouche (1931), Lekagul & Round (1991), MacKinnon & Phillipps (1993), Mann (1990), Medway & Wells (1976), Mees (1975), Melville (1984), Meyer de Schauensee (1984), Perennou *et al.* (1994), Smythies (1981), Stepanjan (1990b), Wang *et al.* (1991), White & Bruce (1986), Xu Weishu & Melville (1994).

7. Royal Tern

Thalasseus maximus

French: Sterne royale **German**: Königsseeschwalbe **Spanish**: Charrán Real

Taxonomy. *Sterna maxima* Boddaert, 1783, Cayenne.
Genus often merged with *Sterna*. Sometimes considered to form superspecies with *T. bergii*. Racial variation questionable. Two subspecies normally recognized.
Subspecies and Distribution.
T. m. albididorsalis (Hartert, 1921) - Mauritania to Guinea, occasionally further S; winters S to Namibia.
T. m. maximus (Boddaert, 1783) - S California to Sinaloa, and Maryland (rarely New Jersey) to Texas, and through West Indies to the Guianas and possibly Brazil, with disjunct breeding populations on Yucatán, and in S Brazil, Uruguay and N Patagonia; winters S to Peru and to Uruguay and Argentina.
Descriptive notes. 45-51 cm; 320-500 g (*maximus* 380-500 g; *albididorsalis* 320-440 g, mean 367 g); wingspan 100-135 cm. Crown and elongated nape feathers black; mantle and upperwing very pale pearl grey; bill bright orange, rarely red; legs and feet black. Slightly smaller than *Hydroprogne caspia*, with more slender bill, and primaries pale grey below, not blackish. Similar to *T. bergii*, but paler above and heavier-billed. Non-breeding adult has mostly white forehead, white crown streaked with black, and black extending from nape forwards to eye; moult begins early, so that forehead and even forecrown often white while still incubating. Juvenile has greyish hindcrown, and white mantle feathers with brown subterminal chevrons and grey tips; flight-feathers grey, also with brown and grey markings; most wing-coverts pale grey, lesser coverts darker; bill and feet yellowish; less brown and black on upperparts than juvenile *T. bergii*. Immature resembles winter adult. Races very similar, *albididorsalis* with smaller wing-bill ratio; if races valid, Patagonian birds need to be examined, as they are more similar to *albididorsalis*.

Habitat. Subtropical and tropical coasts. Breeds on barren sandy barrier beaches, salt-marsh islands, shell bars, dredge spoil, and coral islands. Shuns vegetation. Many colony sites vulnerable to flooding. Breeding colonies typified by inaccessibility, high visibility, absence of mammalian predators, and surrounded by shallow waters near the mouth of bays. Feeds along estuaries, lagoons and mangroves. Outside breeding season, frequents coasts, estuaries, harbours and river mouths, sometimes penetrating a short distance up broad rivers.

Food and Feeding. Mainly small fish (3-18 cm, average 6·7 cm), also squid, shrimps and crabs. In Africa, mainly Clupeidae, Mugilidae, Pomadasyidae, Carangidae, Ephippidae. In Virginia, mainly *Menidia*, *Fundulus*, *Anchoviella*, *Brevoortia*; in Florida *Brevoortia*, *Micropogonias*; in California, relies on Pacific sardine (*Sardinops sagax*). Usually feeds singly or in small flocks, despite gregarious roosting. Flies 5-10 m above water and plunge-dives, but does not submerge; also performs aerial skimming and surface-dipping for offal. Occasionally piratic on conspecifics. Forages mostly within 100 m of shore, but feeds up to 40 km from colony.

Breeding. Lays Apr-Jul in W Africa, Apr in Texas, May from Florida to Maryland, Jun in Cayenne, Nov in Patagonia. Breeds in dense, often very large colonies, often near Laughing Gulls (*Larus atricilla*) and/or *T. sandvicensis*; estimates of 11,000 nests on Cape Romain, South Carolina, in 1947 and 10,000 at Saloum, Senegambia; most colonies 100-4000 pairs. Nests show classical hexagonal packing, with 5-8 nests/m². Occasionally nests singly among other tern species, usually at margin of range. Nest a mere scrape in substrate, occasionally on roofs (Florida). 1 egg (1-10% lay 2), although adults have two brood patches; incubation 25-31 days; chick greyish or buffy, with or without dark spots, soft parts very variable; 45-55 g at hatching; chicks form crèche when disturbed; fledge at c. 30 days; parental care to 5-8 months. Productivity highly variable. First breeding at age 3 or, more typically, 4. Recorded longevity of 17 years certainly an underestimate.

Movements. Post-breeding dispersal N, followed by S migration. In America, winters from South Carolina and Gulf Coast to Argentina, very rare along Peruvian coast. Chicks ringed in South Carolina colonies recovered mainly along Gulf Coast, in Florida and West Indies, but 1 in California; those ringed in Virginia found mainly in Greater Antilles. W African birds disperse N to Morocco, where flocks of up to 200 in Aug 1995; most then move S to winter from Senegal to Angola, with smaller numbers S to Namibia.

Status and Conservation. Not globally threatened. Population declining in several areas. In SE USA, numbers increased in early 1900's and species slowly colonized northwards, breeding as far N as Maryland and rarely New Jersey. E coast population c. 34,000 pairs; Caribbean under 1000 pairs; French Guiana (Cayenne) 1000 pairs, but remainder of South American population not known. Numbers in California have crashed in past 25 years along with virtual disappearance of species' staple food, the Pacific sardine; c. 8500 pairs on Isla Rasa (Gulf of California). About 25,000 pairs in Africa. Colonies subject to flooding; also to egging, formerly in USA, and still in Caribbean. Pesticides potentially important because of large prey size. In South Carolina, sand crabs (*Ocypoda arenaria*) destroyed many eggs. Common Black-headed Gulls (*Larus ridibundus*) take both eggs and chicks; Laughing Gulls take eggs only.

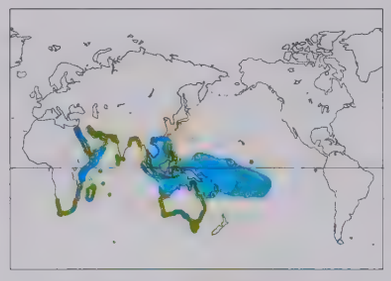
8. Greater Crested Tern

Thalasseus bergii

French: Sterne huppée **German**: Eilseeschwalbe **Spanish**: Charrán Piquigualdo
Other common names: Crested Tern, Swift Tern (Africa)



Taxonomy. *Sterna Bergii* Lichtenstein, 1823, Cape of Good Hope.

Genus often merged with *Sterna*. Sometimes considered to form superspecies with *T. maximus*. Subspecific taxonomy unusually confusing, with many other races proposed, e.g. *bakeri*, *edwardsi*, *halodramus*, *pelecanoides*, *poliocercua*; race *gwendolenae* may not be valid. Six subspecies currently recognized.

Subspecies and Distribution.

T. b. bergii (Lichtenstein, 1823) - Namibia to South Africa; some non-breeders move to S Mozambique.
T. b. enigma (Clancey, 1979) - Zambezi Delta, believed to nest on islands off Mozambique and Madagascar.
T. b. thalassinus (Stresemann, 1914) - Tanzania, Seychelles, Aldabra and Rodrigues I, and possibly this race in NW Madagascar; wanders to S Somalia.
T. b. velox (Cretzschmar, 1827) - Red Sea and NW Somalia E to Myanmar, Maldives and Sri Lanka; W populations winter S to Kenya.
T. b. cristatus (Stephens, 1826) - Malaysia to Philippines and Ryukyu Is, and E Australia to Society Is.
T. b. gwendolenae (Mathews, 1912) - W & NW Australia.

Descriptive notes. 43-53 cm; 320-400 g (*velox* 340-400 g, *thalassinus* 320-350 g, *cristata* 325-383 g); wingspan 100-130 cm. Large tern with white forehead in breeding plumage, when has a glossy black cap and long crest; neck, underparts and secondaries white, latter contrasting with otherwise grey back and upperwing; bill chrome yellow, sometimes tinged greenish at base, or entirely greenish yellow with irregular black blotches; feet black. Differs from *T. bengalensis*, with which often co-occurs, in larger size and longer, yellower bill. Similar to *T. maximus*, but with darker upperparts, slimmer body, and more slender, cold yellow (not orange) bill with steeper gonydeal angle. Non-breeding adult has white crown with some dark spotting, but retains black on hindcrown. Juvenile has crown feathers tipped brownish; upperparts and upperwing very heavily mottled or barred with brown; primaries dark brown, with white on inner webs; secondaries ashy brown with white tips; bill greenish; feet brownish black. Immature resembles non-breeding adult, but has browner crown with pale spots, and brown markings on neck, back and wing-coverts. Races vary mainly in colour tone of upperparts and amount of white on forehead: *enigma* palest, nominate *bergii* with least white on forehead; *velox*, *thalassinus* and *cristatus* very dark above, *velox* with heaviest bill and body, *thalassinus* with broader white band on forehead.

Habitat. Tropical and subtropical coasts and oceanic islands. More marine than *T. maximus*. Nests on offshore islands, low-lying coral, sandy or rocky islets, coastal spits, lagoons, and recently on artificial islets in salt-pans and sewage works within 3 km of coast (S Africa). Forages in shallow waters of lagoons and barrier reefs, in estuaries, along beaches, and also well out to sea. Rests on buoys or on rocks and sandbars, often with other terns and gulls.

Food and Feeding. Feeds mainly on fish (10-15 cm long); also opportunistically on squid, crabs, insects, baby turtles and other aquatic prey. In South Africa 86% of fish is Cape anchovy (*Engraulis capensis*), but 20 fish species represented in 1311 prey items. In W Australia mainly clupeids. Along Great Barrier Reef, 7 fish families represented in diet, mainly clupeids. Usually forages in small groups, flying c. 3-6 m above water and plunge-diving or contact-dipping; juvenile feeds by contact-dipping. Occasionally engages in piracy, but more often a victim, with up to 12% of fish stolen (Australia). Forages mostly within 3 km of colony.

Breeding. Apr-Jun in Indian Ocean, May-Jun in Sudan and S Africa, Aug in Somalia, Sept-Dec in E Australia, Dec-Jan in tropical Australia, Oct in Kenya, Nov in Tanzania; two peaks in Aldabra (Jan and Jul) and in SW Australia (Apr-May and Oct-Nov), but each individual nests only once yearly. Forms large dense colonies (mainly Australia), or very small subcolonies, often fewer than 10 pairs, among gulls, especially Silver Gull (*Larus novaehollandiae*) and Hartlaub's Gull (*L. hartlaubii*). Nest a shallow scrape in bare sand, rock or coral; nests close together (33-44 cm apart), rims often touching. Lays 1 egg in Australia, otherwise 1-2, rarely 3 in Indian Ocean probably result of 2 females laying in same nest; incubation 25-30 days; chick whitish with fine, sparse, black speckles; leaves nest at c. 2 days; fledging c. 38-40 days; dependent at least until 4 months. First breeding usually at age 3, although one record of breeding attempt at 1 year. Productivity 0-0·6/nest. Oldest ringed bird 20 years.

Movements. Movement patterns mostly unknown, and many populations more or less resident around breeding areas. Australian birds disperse several hundred kilometres around colony. Race *velox* disperses mainly within its breeding range, but Middle East birds move S to E African coast after breeding, and winter mainly from Egypt to Kenya, overlapping with *thalassinus*. Non-breeding birds of nominate race overlap with *enigma*.

Status and Conservation. Not globally threatened. Locally vulnerable owing to propensity for nesting in just a few, large, dense colonies. More than 500,000 pairs in Australia, and c. 50,000 pairs elsewhere; c. 33,000 pairs in Middle East including minimum 4000 pairs off Oman, c. 3500 pairs on islands off Saudi Arabia in early 1990's, also 1256 pairs off Abu Dhabi in 1994, and many 1000's in Iran. Race *bergii* has about 5000 pairs in 6-10 colonies, but c. 95% of these in 2 colonies; largest, on Marcus I (NW Pacific), is in a fairly well protected reserve. Many colonies subject to egging and to predation by gulls and ibises, particularly when incubating terns are flushed by raptors or human intruders. Apparently declining in Indonesia owing to egging, but population difficult to assess. Formerly bred in Gulf of Thailand, but not recently.

Genus *STERNA* Linnaeus, 1758

9. River Tern

Sterna aurantia

French: Sterne de rivière **German**: Hinduseeschwalbe **Spanish**: Charrán Indio
Other common names: Indian River Tern

Taxonomy. *Sterna aurantia* J. E. Gray, 1831, India. Monotypic.

Distribution. E Pakistan to S India and E through Nepal to SW China (Yunnan) and Mekong Delta.

Descriptive notes. 38-46 cm; wingspan 80-85 cm. Typical tern, with black crown and lores and deeply forked tail; darkish grey upperparts; bill somewhat stout, bright yellow; iris dark brown; legs red. Non-breeding adult has whitish forehead and forecrown, with black marks around eye to nape; bill dull yellow with dusky tip. Immature grey above, flecked with buffy white and boldly marked with black chevrons; forehead and broad eyeline white; bill dull ochre. 1st-summer very similar to adult, but with a few white feathers on crown and shorter tail streamers.

Habitat. Breeds on sandy islands in freshwater lakes and rivers, and rarely estuaries; shuns mainland sites. Feeds mainly over fresh water. Rare along the coast, where feeds in estuaries and over mudflats. Occurs up to 600 m in Nepal.

Food and Feeding. Mainly fish, small crustaceans and insects. Usually feeds by plunge-diving.

Breeding. One of least studied terns. Breeds mainly Feb-May in dry season, but extreme dates Nov-Jun. First nests often flooded out, and re-laying occurs. Nests colonially, often with other terns, skimmers and Little Pratincoles (*Glareola lactea*); colonies generally contain fewer than 20 pairs. Readily mobs intruders, including hawks and corvids. Nest a shallow scrape on bare sand. Usual clutch 3, rarely 4; incubation reported as 18-19 days, but probably longer; young independent by 3 weeks after fledging. Some nest at 1 year of age.

Movements. Mainly a permanent resident, with some short nomadic movements. A few birds winter on seashores of S Asia.

Status and Conservation. Not globally threatened. Widely distributed in small colonies, but overall status poorly known. No evidence to suggest that species is threatened at present, but many nesting areas are vulnerable to flooding, predation and human disturbance. Now very rare in Thailand, where once not uncommon. Uncommon in S India, and rare along the coast; locally common resident in Nepal.

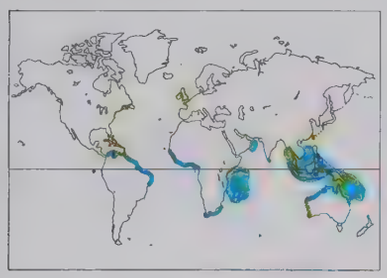
cm 18

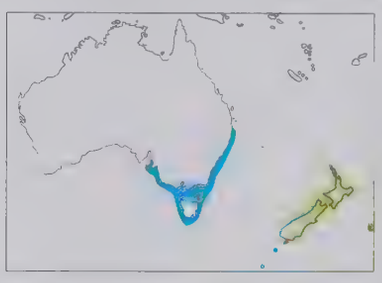


10. Roseate Tern

Sterna dougallii

French: Sterne de Dougall **German**: Rosenseeschwalbe **Spanish**: Charrán Rosado

Taxonomy. *Sterna Dougallii* Montagu, 1813, Firth of Clyde, Scotland.
In some respects intermediate between *Sterna* and *Thalasseus*. Internal taxonomy in need of revision, as subspecific boundaries confused: racial allocation of birds breeding on islets off E Africa requires study, perhaps closer to *bangsi* than to *dougallii*, although included in latter; *arideensis* may not be distinct from *bangsi*; variation of nominate *dougallii* encompasses almost entire range of variation of species. Five subspecies currently recognized.
Subspecies and Distribution.
S. d. dougallii Montagu, 1813 - Nova Scotia to New York and Florida, S through Gulf of Honduras and West Indies to islands off N Venezuela, and also Azores, NW Europe, and E & S Africa from S Somalia to Tanzania and in S Cape Province; American populations may winter mainly in mid-Atlantic, E Atlantic birds winter on coasts of tropical W Africa.
S. d. arideensis Mathews, 1912 - Seychelles S to Madagascar and E to Rodrigues I.
S. d. korustes (Hume, 1874) - Sri Lanka, Andaman Is and Mergui Archipelago (SW Myanmar).
S. d. bangsi Mathews, 1912 - Arabian Sea, Ryukyu Is, coastal China and Taiwan S to Greater Sundas and E to S New Guinea, Solomons, New Caledonia and possibly Fiji; presumably this race on Cocos (Keeling) Is.
S. d. gracilis Gould, 1845 - Moluccas and Australia.



Descriptive notes. 33-43 cm; 90-125 g (average 110 g, New York); wingspan 72-80 cm. Very pale typical tern with very long tail streamers; forehead to nape black; mantle and upperwing very pale grey; tail entirely white and deeply forked; black outer webs on 3 outer primaries only; immaculate white below, tinged pink early in breeding season (pink reduced or absent in tropical populations, and in South Africa appears only during chick phase); legs and feet dull to bright red. Changes in bill colour vary geographically: in N latitudes and in Somalia, bill black with slight red at base at start of breeding, red increasing steadily throughout season until bill half or mostly red as migration begins; Caribbean birds arrive with all black bill, but basal two thirds red by time of egg-laying; in Seychelles, bill all black prior to breeding, fully red at end of cycle. Species differs from *S. hirundo* in shorter wings and longer tail, with faster, shallower wingbeats, different bill pattern, paler plumage, and distinctive rasping "aaask" calls and sharp, high-pitched "chew-ik". Non-breeding adult has forecrown mottled black and white, no pink below, faint dusky bar on lesser coverts, and all black bill. Juvenile heavily barred with black and/or brown crescents on mantle, mottled brownish grey on back and rump; bill and legs dark. Subadult like non-breeding adult, but with white forehead and hindneck, speckled with brownish, and sooty brown mark across crown and ear-coverts to nape; legs usually darker. Races differentiated by wing length, and bill length and colour, but these parameters vary with latitude; apart from *korustes*, which has both shorter wing and bill and greyer upperparts, all racial differences covered by variation within nominate *dougallii*.
Habitat. Breeds on sandy, rocky or coral islands, often with dense vegetation in temperate areas, or barren islets in tropics; rarely breeds on salt-marsh. Off Kenya, nests on mushroom-shaped blocks of coral up to 18 m above sea. On Long I, New York, some birds nest under boulders. Feeds along tide-rips, in estuaries and several kilometres offshore.
Food and Feeding. Diet much less varied than that of *S. hirundo*, with which it often nests: almost exclusively small fish, rarely insects and marine invertebrates. Strong preference for sandeels (*Ammodytes*) and various clupeids in N latitudes. In South Africa 11 species of fish recorded, mainly ratfish (*Gonorhynchus gonorhynchus*, mean length 8 cm). In W Africa often snatches sardines (*Sardinella*) from beach. Often feeds in flocks with other species. Plunge-dives from greater heights and submerges more deeply (up to 50 cm) than *S. hirundo*. Also feeds by aerial-dipping for small fish driven to surface by predators, and contact-dips for small fish and invertebrates over shoals of bonito (*Sarda*), tuna (*Thunnus*) and bluefish (*Pomatomus saltatrix*). Scavenges behind fishing boats. Sometimes piratical.
Breeding. Apr in W Australia, India, Sri Lanka and Madagascar, May-Jun in NE USA and Europe, Jun in Somalia, Jul-Aug in Kenya and Seychelles, Jun-Oct in South Africa; lays earlier in good food years. Usually in mixed colonies, but monospecific colonies of up to 4000 pairs in Madagascar and 8000 pairs on Kiunga Is, Kenya. Colonies often very dense, with inter-nest distances 40 cm, particularly in Africa; less dense in temperate regions. In North America and Europe almost always nests with *S. hirundo*, and occasionally interbreeds; in India and E Australia usually with *S. sumatrana* and often *Thalasseus bergii*. Nest usually a bare scrape in sand or on coral rubble or bare rock; sometimes on vegetation, often without nest material; in NE USA and Europe nest usually beside or under vegetation, rocks or wood, so eggs barely visible from above, but in Caribbean and Australia often fully exposed on bare substrate. Usually 2 eggs, with tendency towards 1 in poor food years or in tropics; average 1·4 in Kenya, 1·3 in South Africa, but only 1 in Seychelles. Incubation 22-26 days; chick mottled dark, with dark grey chin and throat and white to buffy white underparts, not speckled like most *Sterna*; average hatching weight 14·8-16·0 g; hides in vegetation near nest, until fledging at 23-30 days. Productivity often 1-1·5 young raised/nest, but in West Indies less than 1 largely as a result of crab predation on hatchlings; in South Africa 0·1-0·4/nest.
Movements. Palearctic birds winter W Africa, mainly between Guinea and Gabon; usually remain in tropics in 2nd and even 3rd years. Wintering grounds of American populations inadequately known, though some apparently winter on N coast of South America. Birds from NE USA gather in large post-breeding flocks in Aug-Sept, moving N to rich fishing areas on Maine coast; then migrate S, passing offshore, and species is very rare visitor to the Carolinas; common migrant off Trinidad and the Guianas, but winters further S or at sea. Essentially absent from Caribbean Oct-Apr, but wintering grounds uncertain; some recoveries from Guyana suggest wintering somewhere in South America, perhaps mixed with NE birds; a juvenile ringed Long I, New York, recovered on Pacific coast of Colombia. Few sightings in Caribbean Colombia, perhaps of birds from Venezuelan colonies. Adults from NE USA have lingered in Puerto Rico during breeding season, but do not mix with resident *S. dougallii*. E African birds mostly absent Nov-May, may move to S Africa. Winter quarters of most other populations (e.g. of Great Barrier Reef) unknown.
Status and Conservation. Not globally threatened. NE North American and European populations much reduced, and considered endangered; Caribbean population threatened. World population c. 50,000 pairs. In North America numbers peaked before 1950's, declining steadily to mid-1980's, but now stable at c. 3000 pairs. European population declined drastically, and reduced in UK to 57 pairs in 13 colonies by 1991; 1995 was good year in Europe, with over 1700 pairs breeding, mainly in Ireland and Azores. Egging is continual threat and significant cause of mortality in Caribbean and E Africa. In NE South America and W Africa, wintering adults are captured for food by netting, baited hooks, or snaring; this may account for population decline, at least in part. Colonies of *arideensis* have disappeared in Seychelles, and the surviving colony on Aride has declined from 4000 pairs in 1975 to 1000 in 1988, perhaps due to increased long-line fishing. Compared with *S. hirundo*, adults, if trapped for ringing early in incubation, are more likely to abandon nests, and in certain colonies some do not return for hours after release. In Puerto Rico, land crabs (*Gecarcinus*, *Coenobita*) cause heavy chick mortality. On Long I, New York, ants enter pipping eggs and kill hatchlings. Tick infestation sometimes causes abandonment in Seychelles and perhaps E Africa.

11. White-fronted Tern

Sterna striata

French: Sterne tara **German**: Weißstirn-Seeschwalbe **Spanish**: Charrán Maori

Taxonomy. *Sterna striata* Gmelin, 1789, New Zealand.
Sometimes considered monotypic, and validity of races requires study. Three subspecies currently recognized.
Subspecies and Distribution.
S. s. incerta Mathews, 1912 - Flinders I and Cape Barren I, off NE Tasmania.
S. s. striata Gmelin, 1789 - North I, South I and Stewart I (New Zealand).
S. s. aucklandorna Mathews, 1929 - Chatham Is, Auckland Is, and possibly Snares Is.

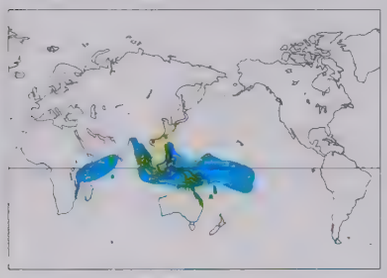
Descriptive notes. 39-42 cm. Crown black, with narrow white forehead and lores; upperparts pale grey, including long tail which extends beyond folded wingtips; underparts white, sometimes with faint pink or rusty tinge to breast; iris brown; bill black; legs dark brownish. Non-breeding adult has more extensive white forehead and white spotting on crown, with black spot before eye; resembles non-breeding *S. hirundo*. Juvenile has brown mottling on upperparts, white streaking on dark nape, blackish outer wing and large black triangular patch on inner forewing. Races differ little in appearance.
Habitat. Coastal areas, nesting on rocky or sandy beaches and shingle islands in rivers, also on coastal cliffs and deserted barges, often close to the surf. Feeds along shore and in bays. In winter, also oceanic.
Food and Feeding. Almost exclusively fish; also shrimps. Feeds in surf zone or several kilometres out to sea, often in flocks. Plunge-dives from 7-10 m, with or without hovering; also feeds by contact-dipping. Frequently victimized by skuas.
Breeding. Laying Oct-Dec. Most colonies contain 100-500 pairs, but solitary pairs reported at margin of range. Some colonies stable for many years, but on Bass Strait islands (*incerta*) frequently changes sites from year to year. Forms a hollow in sand or small rocks, sometimes assembling large nest of plant stems. 1-2 eggs, average 1·54 in Tasmania; incubation unrecorded; chick whitish to brownish, and speckled; brooded for 4-6 days, then may form crèche; fledging 29-35 days; remains dependent for 3-6 months. Storms cause high winter mortality of adults. First breeding at 2 years. Recorded longevity of 20 years.
Movements. Winter visitor to E Australia, from S Queensland to Tasmania and W to South Australia. Some northward dispersal in New Zealand. Race *aucklandorna* recorded as straggler to Campbell I.
Status and Conservation. Not globally threatened. About 500,000 pairs breed in New Zealand. The Bass Strait form, putatively considered a separate subspecies, is rare; its breeding sites were not discovered until 1979, although historical records of eggs from SE Tasmania date back to 1888.
Bibliography. Blakers *et al.* (1984), Chambers (1989), Davis & Mykytowycz (1982), Flegg & Madge (1995), Hindwood (1946), Hitchcock & Favaloro (1951), Imber & Crockett (1970), Lindsey (1992), Macdonald (1988), Marchant & Higgins (1996), Napier (1982), Oliver (1974), Pizzey & Doyle (1980), Robertson (1985), Schodde & Tidemann (1986), Serventy *et al.* (1971), Simpson & Day (1994), Slater *et al.* (1989), Soper (1976), Trounson (1987), Whinray (1980, 1982).

12. Black-naped Tern

Sterna sumatrana

French: Sterne diamant **German**: Schwarznacken-Seeschwalbe **Spanish**: Charrán de Sumatra

Taxonomy. *Sterna Sumatrana* Raffles, 1822, Sumatra.



On following pages: 13. South American Tern (*Sterna hirundinacea*); 14. Common Tern (*Sterna hirundo*); 15. Arctic Tern (*Sterna paradisaea*); 16. Antarctic Tern (*Sterna vittata*); 17. Kerguelen Tern (*Sterna virgata*); 18. Forster's Tern (*Sterna forsteri*); 19. Trudeau's Tern (*Sterna trudeaui*).

Thought to be closely related to *S. dougallii*, with which sometimes nests, but chick pattern very different. Sometimes considered monotypic, but divided into races on basis of shape. Two subspecies recognized.

Subspecies and Distribution.

S. s. sumatrana Raffles, 1822 - Andaman and Nicobar Is E to S Japan and China, and S through Malaysia, Philippines, Indonesia and New Guinea to NE & E Australia and Pacific islands (Yap, Marshall Is, Ponapé, Micronesia), with breeding also suspected (at least formerly) in Bengal, Bangladesh and S Myanmar; birds from Japan and China winter to S.

S. s. mathewsi Stresemann, 1914 - Aldabra, Amirante, Chagos and Maldive Is, W Indian Ocean.

Descriptive notes. 34-35 cm; 98-100 g. Forehead and crown white; black band from eyes around nape, in side view appearing to sweep sharply down back of neck, setting off white crown; upperparts very pale grey; tail white with grey centre, deeply forked; outer web of outermost primary black; underparts white, often with rosy tinge; bill black, occasionally with slight yellow tip; legs black. Non-breeding adult similar, but nuchal band reduced. Juvenile has buffy head mottled with grey or black, black nape, and pale grey upperparts with blackish chevrons; lacks pink tinge below. Race *mathewsi* has shorter wing and longer bill.

Habitat. Frequents small rocky, coral and sandy offshore islands, reefs, sand spits and rocky cays. Feeds in atoll lagoons and close inshore over breakers, but sometimes at sea.

Food and Feeding. Feeds mainly on small fish, 4-8 cm long: Engraulidae, Exocoetidae, Atherinidae, Clupeidae, and secondarily other families (Mugiloididae, Blennidae, Hemiramphidae, Scombridae, Pomacentridae). Almost always forages singly, occasionally in company of *Anous minutus* over predatory fish. Feeds mainly by shallow plunge-diving, also by surface-dipping and occasionally swim-dipping. In N Great Barrier Reef feeds mainly inshore over reef flats; 80% of feeding trips within 2 km of colony.

Breeding. May in India and Polynesia, Sept-Nov in Indian Ocean, Sept in tropical NE Australia, and Nov-Dec on S Great Barrier Reef. Usually forms small colonies of 5-20 pairs, sometimes up to 200 pairs; colonies often monospecific, but may be associated with *S. dougallii* or *S. anaethetus*; not highly synchronous. Nest an unlined depression in sand (Australia) or in gravel or pockets on coral banks (Maldives), close to high tide line, sometimes demarcated with shell or with fragments of coral; sometimes on or next to vegetation. May also nest on artificial structures. 2-3 eggs on Andaman Is, but usually only 1-2 in Indian Ocean and 1 at Cook Is, average 1·5 on Great Barrier Reef; incubation 21-23 days; chick white to yellow-buff, usually with large blackish marks on body and fine blackish spots on head (sometimes unmarked), and reddish orange bill and legs; brooded or shaded for 7 days; adults mob predators and also give plover-like "ungulate" display with upright posture and spread wings. Many nests lost to flooding; typically, 1-20% of eggs result in fledged young.

Movements. Resident around some colonies and disperses to sea from others. Migration routes, if any, not documented. Straggler to Line Is (C Pacific); vagrant to S Africa (*mathewsi*).

Status and Conservation. Not globally threatened. Total population not well known. Thousands nest throughout SW Pacific, which appears to be stronghold of species, but most archipelagos hold only small numbers, and species apparently absent from central islands of S Pacific. Has declined in Malaysian waters, where population now under 2000 pairs. One of commonest seabirds in Indonesia, where c. 50 known nesting sites, each with up to 100 pairs. Species is probably secure because of its many small colonies.

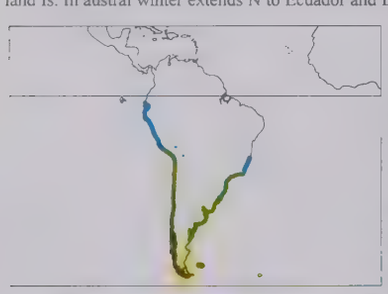
13. South American Tern



Sterna hirundinacea

French: Sterne hirundinacée **German**: Falklandseeschwalbe **Spanish**: Charrán Suramericano

Taxonomy. *Sterna hirundinacea* Lesson, 1831, Santa Catarina, Brazil.

Monotypic.

Distribution. Coasts of S Peru and Espírito Santo (CE Brazil) S to Tierra del Fuego, including Falkland Is. In austral winter extends N to Ecuador and Bahia (CE Brazil).

Descriptive notes. 41-43 cm; 172-196 g; wingspan 84-86 cm. A typical *Sterna*, with black cap and pale grey upperparts; underparts pale grey, contrasting somewhat with white cheeks and white undertail-coverts; bill and legs all red. Very similar to *S. hirundo*, but larger, roughly size of *Thalasseus sandvicensis eurygnatha*; has longer bill and tail, and greyer underparts. Non-breeding adult has white forehead and forecrown. Juvenile has creamy white crown with dark mottling; blackish barring on upperparts, particularly on upperwing-coverts; dark grey primaries; whitish tail feathers with dark outer webs; black bill and dirty yellow feet.

Habitat. Almost exclusively coastal. Breeds on sandy and rocky beaches, tops of cliffs, and often on small islands. Non-breeders frequent coastal waters, beaches, estuaries and harbours.

Food and Feeding. Small fish and crustaceans; probably also takes insects. Feeds mostly by plunge-diving. Often follows schools of porpoises or predatory fish.

Breeding. Lays Apr-Jun in Brazil (Espírito Santo to Santa Catarina), early Nov in N Argentina and Uruguay, and early Dec in S Argentina. Forms colonies of dozens to 10,000's of pairs; in dense areas, 3 nests/m². Changes colony site frequently. Forms nest scrape in sand or fine gravel, sometimes surrounded by small shells; often on sandy or gravel spit or beach ridge, occasionally with dense vegetation, but also uses artificial structures. 2-3 eggs; incubation 21-23 days; incubating adults usually not aggressive to human intruders in remote colonies, but mob vigorously in more disturbed colonies; chick very variable, from olive-buff to grey, mottled dark, with black throat and dirty white underparts; fledging 27 days. Hatching success 73%; fledging success 0-58 chicks/pair.

Movements. Present in Tierra del Fuego Nov-Apr, where a few birds remain all year. After breeding, however, most move N along coast to Uruguay, where this is commonest tern; common also in Chubut, S Argentina. In austral winter, ranges N to S Ecuador on Pacific coast and to Bahia, Brazil, on Atlantic coast.

Status and Conservation. Not globally threatened. Total population inadequately documented, and many colonies vulnerable to human disturbance. Abundant breeder on Argentine coast of Chubut, with "tens of thousands of pairs" nesting at Punta Tomba in 1969, compared with estimate of 67,500 nests in 1877. More recent survey data required, particularly because of greatly increased ecotourism. Colony exceeding 1000 pairs rediscovered in S Peru in 1995.

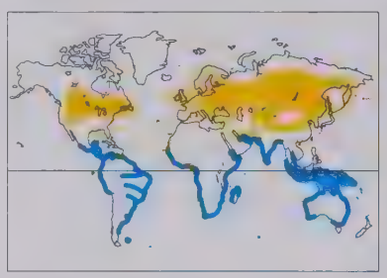
14. Common Tern

Sterna hirundo

French: Sterne pierregarin **German**: Flußseeschwalbe **Spanish**: Charrán Común

Taxonomy. *Sterna Hirundo* Linnaeus, 1758, Sweden.

In North America, genetic studies of populations in Minnesota and Wisconsin and ringing studies in NE USA reveal high degree of gene flow, despite colony site tenacity. C Asian *minussensis* often considered to be no more than a hybrid form between nominate *hirundo* and *longipennis*. Four subspecies normally recognized.



Subspecies and Distribution.

S. h. hirundo Linnaeus, 1758 - North America to N South America, Atlantic islands, Europe, N Africa (Tunisia) and W Africa (Mauritania, Senegal, erratically Nigeria), through Middle East and Black and Caspian Seas to Yenisey Valley; winters S of Tropic of Cancer.

S. h. minussensis Sushkin, 1925 - C Asia through Transbaikalia to N Mongolia and S Tibet; winters mainly N Indian Ocean.

S. h. tibetana Saunders, 1876 - W Mongolia S to Kashmir, Tibet and Sichuan, at high altitudes; winters mostly E Indian Ocean.

S. h. longipennis Nordmann, 1835 - NE Siberia S to NE China (C Heilongjiang to Inner Mongolia and Shanxi); winters SE Asia to Australia.

Descriptive notes. 32-39 cm; 97-146 g (average 120-135 g in breeding season, 102 g in winter); wingspan 72-83 cm. Typical tern; forehead and crown black; back and upperwings grey; tail white, with grey outer web to outer rectrices; underparts white with greyish wash, sometimes faintly suffused with pink early in breeding season; bill red with black tip; legs red; long, forked tail reaches wingtips at rest. In all plumages, but especially in summer and autumn, outer 5 primaries have conspicuous dark outer webs, compared with uniform grey upperwing surface of *S. paradisaea*. Non-breeding adult has forehead white, crown black with white streaks, and prominent dark bar on lesser coverts; underparts greyish; bill blackish, with red only at base; legs duller red to blackish red. Juvenile grey above, barred with dark grey or brown; blackish carpal bar on wing (darker than in *S. paradisaea*), and dark secondary bar; bill orange at base, soon becoming dusky grey-brown. In winter, nearly half of birds seen off W Africa are in "*portlandica*" (1st-summer) plumage, with white forehead and black mid-crown and hindcrown, and very worn, dark outer primaries and secondaries. Montane race *tibetana* slightly darker above and below, with shorter bill; *longipennis* has black bill and red-brown to blackish brown legs, but racial identification difficult when mixed with black-billed wintering birds.

Habitat. Breeds in both coastal and inland areas, from sea-level to 4000+ m. Wide variety of habitats including sandy barrier beaches; vegetated inter-dune areas; sandy, rocky, shell or well vegetated islands in estuaries, lakes and rivers; grassy plateaux atop sea cliffs (Madeira). Where co-occurs with *S. paradisaea*, present species uses grassier areas. Adapts to artificial nesting substrates. In Europe, occupies middle reaches or confluences of rivers. Winters mainly on coastal estuaries and up large rivers. Frequents harbours, jetties, piers and beaches.

Food and Feeding. Mainly small fish, particularly *Ammodytes*, *Menidia*, *Fundulus*, *Tautogolabrus*, *Clupea*, *Brevoortia*, *Scomber*; in W Africa mainly *Engraulis*. Occasionally crustaceans, insects and fish offal. Prey availability varies greatly within and between seasons, and this species more opportunistic than *S. dougallii*; when preferred prey (*Ammodytes*) fails, readily switches to other fish. In Italy 91% of fish 6-15 cm. In Ukraine, 83% of regurgitations and stomachs contained fish, and 27% insects. Wintering flocks in C Peru feed mainly over planktonic crustacea; in S Peru mainly by aerial-dipping in wave-washed zone on abundant mole crabs (*Eremita analoga*); in North Carolina, occasionally switches to *Eremita talpoida* when these become superabundant. In NE South America, where food limited (body weights average 99-104 g), relies on human fishing activities for food, and in turn is harvested commercially using small fish as bait. Feeds in dense flocks over ocean, but some maintain individual feeding territories along shorelines. Most forage 5-10 km from colony, but some feed at sea over 15 km from shore. Feeds mainly by plunge-diving, also by contact-dipping and aerial-dipping, and occasionally aerial hawking. Kleptoparasitism common in some colonies or in conditions when food availability limited; often victimized by skuas.

Breeding. Laying mainly Apr-Jun. Mainly colonial, often in thousands, but sometimes solitary. Inland colonies smaller than coastal ones; at N edge of British range, colonies hold fewer than 20 pairs; many colonies of 100-1000 pairs, but up to 6000 pairs; average 263 pairs in Britain, 95 in Virginia, USA; Dutch colonies on Griend held 25,000 pairs until 1955; race *tibetana* usually in small, widely dispersed colonies. Nest spacing ranges from 40 cm (or less with visual barrier) to 5 m; mortality and piracy higher in dense areas. Favours edges of bare sand among moderate vegetation, rocks, or logs, but also uses open substrates with little or no vegetation; on beaches shows preference for nesting beside open area on margin of vegetation, and in marshes prefers edges of mats of dead vegetation, but occasionally on muskrat houses or on floating cattail (*Typha*) mats; on rocky islets, prefers grassy to rocky substrates; readily nests on artificial rafts. Forms shallow depression, sometimes lined and/or with rim of stones, debris, etc., occasionally roofed over with vegetation; often placed near some vertical object such as rock, shell, plant or artifact, which may later provide shelter for chicks and may facilitate nest identification. Clutch and egg sizes depend

on food availability; at higher latitudes normally 3 eggs, but usually 2 in poor food years, or at lower latitudes or after heavy storms; average clutch in temperate regions 1·7-2·7, depending on food availability; in W Africa mean 1·5-2·7; in Cuba mean 1·1; older adults lay earlier and larger clutches, and have higher productivity in good food year; chicks from larger eggs have higher survival. Incubation 22-28 days, depending on disturbance; on extremely hot days, adults wet belly feathers to cool eggs; chick buffy brown above with bold black spots (0·5% are immaculate buffy), black chin, and white below, lacking grey cast of *S. paradisaea* chicks; mean hatching weight 14·8 g in New York, 18-21·4 g in Poland; by day 6 chick recognizes parental landing call; fledging 24-28 days. Productivity very variable, from 0 to 2 young/nest; usually higher on beaches, mostly 1·1-1·5/nest, than on marshes, which are subject to flooding. Annual adult mortality 7-17% in different studies, but sometimes much higher due to viral epizootics in Africa; 8-14% of fledged young are recruited as breeders. Adults tend to return to same colony and subcolony where previously successful; chicks often settle in another colony. Very few breed at 2 years, few at 3, and most at 4. Recorded longevity of 25 years.

Movements. Palearctic birds move S late Aug to Oct, returning in Mar-Apr. European birds pass quickly down NW African coast to winter in W & S Africa; a few may remain off Iberia. Northernmost breeders winter further S. Abundant migrant in NE Africa, mainly from E Europe, with some inland migration through Rift Valley. Birds from Black Sea have been recovered in Somalia. Nominate race common in winter along W coast of S Africa, and a few also reach W Australia. C Asian birds winter mostly on coasts of Indian Subcontinent, and SC Asian *tibetana* winters from E India to Malaysia, a few reaching Natal. Chinese breeders migrate to coasts of China and SE Asia, and NE Asian birds move through Japan and Philippines to New Guinea, Indonesia and Australia. North American birds migrate along Atlantic coast, through West Indies, reaching the Guianas in late Oct, and wintering mostly from Brazil to Argentina; others move to Pacific coast of C America and S to S Peru, some wintering as far N as Gulf of California. Nearctic breeders do occasionally cross the Atlantic: one ringed on Long I, New York, was recovered in W Africa.

Status and Conservation. Not globally threatened. World population at least 250,000, possibly 500,000 pairs: c. 35,000 pairs in E North America, plus 140,000 in Europe; possibly several 100,000's pairs in former USSR. Very sparse breeder in tropical America. Stable in Europe, spreading in some areas and decreasing in others from 1960's through 1980's. Populations greatly reduced in 19th century by egging, hunting and millinery trade, and human development of coastal habitat has eliminated colonies from 19th century to present. Populations recovered with protection, but began to decline again in late 20th century, with loss of many colonies due only partly to habitat development. Many factors implicated in different locations. In parts of W Africa, human predation results in only 12% of chicks fledging. Many colonies jeopardized by flooding, vegetation overgrowth, gull colonization, human disturbance and off-road vehicles, while quarrying of shingle islands reported in Italy. Flooding sometimes leads to complete failures; spring floods often eliminate early nesters. Oiling affected 50% of birds wintering in Trinidad, but did not always result in poor body condition. Pollutants cause eggshell thinning, but are usually not a major contributor to hatching failure. Rat predation on eggs often significant; unusual egg predators include garter snakes (*Thamnophis sirtalis*) and migrating Ruddy Turnstones (*Arenaria interpres*); nocturnal mammalian and avian predators often cause adults to leave, and in addition to predation, some chicks die of chilling. Artificial nesting rafts have proved effective in places where suitable habitat is lacking, or where human disturbance is a problem.

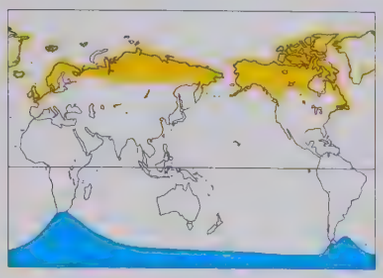
15. Arctic Tern



Sterna paradisaea

French: Sterne arctique **German**: Küstenseeschwalbe **Spanish**: Charrán Artico

Taxonomy. *Sterna Paradisaea* Pontoppidan, 1763, Christiansø Islands, Denmark.
Listed as *S. macrura* in many older works. Monotypic.

Distribution. Iceland, Britain and Netherlands through Scandinavia, and across Asia, almost exclusively N of Arctic Circle, to Bering Strait, with isolated breeding sites in Kamchatka, and northernmost breeding area in Franz Josef Land; Aleutians and N Alaska across to NW & NE Greenland, and S to British Columbia and New York, with isolated colony in NW Washington. Migrates to Antarctica, where spends much of N winter in pack ice zone.

Descriptive notes. 33-36 cm; 86-127 g; wingspan 76-85 cm. Forehead and crown black; rest of plumage rather uniform grey, including underparts, but with narrow white cheeks and white rump and tail, latter with very long streamers; underparts slightly duller grey, extending onto throat and setting off white cheek; outer primaries have inner webs grey, with narrow black line along tips; more pale on secondaries, resulting in a translucent "window" in flight; bill usually completely bright red, but rarely with dark tip; legs red. Very similar to *S. hirundo*, but darker below, with narrower wings and longer tail streamers, shorter legs and shorter, all red bill; lacks dark "wedge" on primaries shown by *S. hirundo*. Similar to *S. vittata*, but is not in breeding plumage when they co-occur. Plumage pattern intermediate between *S. hirundo* and *S. repressa*, and pale cheek can also suggest differently structured *Chlidonias hybridus*. Non-breeding adult has white forehead, and sometimes shows dark carpal bar like *S. hirundo*; bill and legs blackish. Juvenile has dark mantle and upperwing (including greater coverts), with broad white area on secondaries and inner primaries; carpal bar paler and greyer than in *S. hirundo*; bill blackish with pinkish base, becoming all blackish by time birds migrate.

Habitat. Temperate to high Arctic regions, mainly coastal, but also far inland. Nests on shingle beaches, gravel ridges (preferring sandy pockets), earth dykes, bog hummocks, tundra, lichen-covered rocks, barren fields, peat moss, grassy meadows, and islands in lakes and coastal lagoons; also on inland heath or pasture. Vegetation cover ranges from less than 5% to 40%. Prefers more barren areas than *S. hirundo*, and where both occur together it occupies rocky shore more than grassy heath. Fishes in ice-filled bays and offshore, and over wet tundra and ponds. In winter more pelagic than *S. hirundo*, ranging from open sea to pack ice zone. Often seen resting on flotsam.

Food and Feeding. Mainly small fish; also crustaceans, molluscs and insects; amphipods and euphausiids important in certain areas. In early spring occasionally feeds on berries; readily accepts fish offal and even bread; also takes caterpillars off grass, or lands to pick up earthworms. In Finland increasingly reliant on chironomids, which are now increasing in number owing to eutrophication. Many studies indicate diverse diet, with fish predominating. In E North America, chicks fed mainly sandeels (*Ammodytes*) up to 9 cm long and capelin (*Mallotus villosus*), but at Petit Manan (Maine) main fish fed to chicks were various clupeids. In Iceland and N Europe, chicks fed mainly sticklebacks (*Gasterosteus aculeatus*), but also locally crustaceans (*Gammarus, Thysanoessa*). In Britain, at Farne Is, 95% fish, mainly sandeels and herring (*Clupea harengus*), while at Coquet I clupeids became more important as season advanced. In Murmansk, adults had more varied diet (only 50% fish) than chicks (88% fish). When preferred prey (*Ammodytes*) fails, does not readily switch to alternative prey. Very varied foraging methods: hovers and plunge-dives for fish, and hover-dips for fish fry; takes chironomids by flying at height of c. 2 m and dipping to water surface, catching up to 20 prey/minute. Also feeds from perch near water or by surface-dipping. Kleptoparasitism infrequent, but pirates from Atlantic Puffins (*Fratercula arctica*) on Faeroes; often a victim of piracy from skuas and *S. hirundo*. Has daily feeding cycles, even in continuous daylight; some feeding occurs at night when prey close to surface. Feeds mainly within 3 km of colony, but up to 20 km and occasionally 50 km from colony.

Breeding. Laying May-Jun in S of range, Jul in N; varies also with temperature and food availability. Colonies range from few pairs to 300, mostly 5-25; occasionally solitary, but in Baltic 10% of nests solitary; fewer than 2% of colonies exceed 1000 pairs. Often changes sites from year to year, but some colonies persist many years; some birds have strong territory fidelity. Will nest on artificial structures. Forms a shallow scrape, often unlined; nests often more than 10 m apart, but occasionally less than 1 m. 2-3 eggs, average 1·4-2·9, lower on offshore islands and in high Arctic, and in years with food scarcity; incubation 22-27 days; chick usually brownish (oceanic coasts) or usually grey (Baltic), with greyish cast to belly, compared with immaculate white underparts of downy *S. hirundo*; hatching weight 14 g; fledging 21-24 days. Chick survival influenced mainly by hatching sequence and number of siblings, and also by egg size and hatching weight. Productivity reports variable, c. 0·23-1·25 young/pair; productivity increases until age c. 9, then declines. First breeding usually at 4 years, rarely 3 or 5; 3-year-olds unsuccessful. 1st-year survival 80·5%, adult 87-88%. Recorded longevity of 34 years.

Movements. Renowned for exceptionally long and unparalleled migrations between high Arctic breeding sites and Antarctic wintering grounds. Birds from Finnish archipelago depart in Jul; high Arctic birds may linger until mid-Sept. Most migration well offshore. From Siberia and W North America, moves S through E Pacific. Southbound migrants in Atlantic move SE, and juveniles reach W Africa by Aug; some remain off equatorial Africa through winter. Reaches S Africa by Oct, and many continue ESE to edge of pack ice in Nov. Crossing of Antarctic sea aided by westerly winds which drift some birds E in Southern Ocean. Many winter in Antarctic pack ice between Magnet Bay and Oates Land, with some reaching W to Weddell Sea. Accidental in S South America and New Zealand. Return migration mostly in W Atlantic, but mainly offshore. Rare in West Indies and Gulf of Mexico. Common migrant off S Africa (Oct-Nov and May), including both Nearctic and Palearctic birds.

Status and Conservation. Not globally threatened. Widespread colonies at high latitudes in North America and Eurasia, and species common along most of Greenland coast, but many populations have apparently declined. Has increased in many parts of Scandinavia, however, partly due to reduction in egging. Total population may be 500,000 pairs, including several 100,000's in former USSR, 100,000 in Iceland, 20,000 in Norway, c. 44,000 in Britain (of which c. 66% in Orkney and Shetland) and 2500 in Ireland. Nearctic population not censused: Alaskan coastal population estimated at 12,500, but inland population may be much greater. Species remains vulnerable because of dietary habits, and there are some episodes of mortality from red tide. Recent massive declines in N Britain attributed to collapse of stocks of sandeels, the terns' staple food there (see page 642). On N shore of Gulf of St Lawrence, populations of both this species and *S. hirundo* experienced 5·7% growth from 1977 to 1982, but only 0·4% growth over the next 6 years. In N Atlantic, Svalbard population may be vulnerable to oil, particularly in post-breeding period.

16. Antarctic Tern

Sterna vittata

French: Sterna couronnée **German**: Antarktikseeschwalbe **Spanish**: Charrán Antártico

Taxonomy. *Sterna vittata*, Gmelin, 1789, Kerguelen Island.
Birds of St Paul and Amsterdam Is sometimes included in nominate *vittata*; further study required. Six subspecies recognized.
Subspecies and Distribution.
S. v. tristanensis Murphy, 1938 - Tristan da Cunha, Gough, and possibly Amsterdam and St Paul; single breeding report from South Africa questioned, but based on a ringing recovery.
S. v. georgiae Reichenow, 1904 - South Georgia; birds of South Orkney Is, South Sandwich Is and Bouvetøya I possibly of this race.
S. v. gaini Murphy, 1938 - South Shetland Is; presumably this race breeds S to Marguerite Bay on Antarctic Peninsula.
S. v. vittata Gmelin, 1789 - Prince Edward I, Marion I, Crozet Is, Kerguelen Is, and (probably this race) Heard I.
S. v. bethunei Buller, 1896 - Stewart I, and Snares Is, Auckland Is, Bounty Is, Antipodes Is and Campbell I.
S. v. macquariensis Falla, 1937 - Macquarie I.
Sometimes said to breed (*vittata*) on Ascension and St Helena, but almost certainly erroneous.

Descriptive notes. 35-40 cm; 150-180 g (average summer 167-170, winter 197-205 g; *bethunei*, Campbell I, 114-171 g); wingspan 74-79 cm. Forehead to nape black; upperparts pale grey, with contrasting white rump and forked tail; variably grey to black outer web to outer primary; grey-white below, with white undertail-coverts; eye brownish black; bill and legs red. Distinguished from *S. paradisaea* (which, in same region, is normally in winter plumage) by longer legs, and shorter tail with paler webs to outer feathers. Separated from *S. virgata* by white, rather than smoky grey, uppertail-coverts and underwing. Non-breeding adult similar, but forehead white, crown streaked with white, and underparts white; bill and legs variable, from reddish black to dull red. Juvenile has white forecrown streaked with black, and dark brownish grey to blackish hindcrown; grey above, with heavy black and buff bars; white below with finer barring; bill and legs black. Scaly dark tips to feathers wear quickly, hence juvenile plumage changes without moult. 1st-years have white forehead, whiter underparts and dull reddish black bill. Races vary in size and plumage tone: *gaini* largest, followed by *tristanensis*, with *georgiae* smallest but long-winged; upperparts darkest on Kerguelen I (nominate *vittata*) and palest in Antarctica (*gaini*).
Habitat. Rocky islets, with or without vegetation. Often near other seabirds. Often nests on cliffs, but also gravel and rocky beaches, and on Auckland Is sometimes in sparse scrub. Formerly sandy beaches on Tristan da Cunha, but after rats introduced shifted to ledges on offshore stacks. In Bounty and Snares Is nests solitarily on cliff ledges, since sea lions pre-empt flat areas; on Amsterdam I, 200 pairs breed on coastal cliffs inaccessible to cats. Outside breeding season, seeks ice edges in Antarctica, and in South Africa frequents rocky headlands and beaches.
Food and Feeding. Diet almost exclusively small fish (particularly notothenioids) in some places; polychaetes and limpets at Heard I; mainly crustaceans at Kerguelen and Campbell; fish and euphausiids in Antarctica; fish, euphausiids and amphipods at Snares. Occasionally takes insects, scavenges in intertidal zone, or follows boats for offal. Forages mainly in inshore waters, singly or in flocks. Obtains food mainly by plunge-diving. May defend good feeding grounds. Feeding significantly impaired by high wind or seas; plunge-dives over calm water, but switches to contact-dipping in rougher water.
Breeding. Mainly Nov-Dec, with some variation depending on climate and food availability: Oct-Nov in Snares, Nov-Jan on Campbell, Nov in Antarctica, Dec-Feb on Marion and Crozets, Feb-Mar in Antipodes; on Kerguelen I nests Dec-Feb, whereas *S. virgata* nests Oct-Dec. Forms loose colonies of 5-20 pairs, occasionally 40, often solitary, but in S Shetlands several colonies exceed 1000 pairs. Nest a depression or scrape in rock, cliff ledge, soil, sand or vegetation mat, often with pits of pebble or shell. 1-2 eggs (1 on Kerguelen, 2 in Antarctica); incubation 23-25 days; chick buffy with heavy black spots above, greyish white below, throat dark grey, bill flesh to blackish, and feet pale flesh to reddish black; fledging 27-32 days; some post-fledging parental feeding. Productivity low on Heard I; inadequately studied elsewhere. Skuas kill adults, and many chicks die from exposure to harsh weather. Some eggs lost to gulls and skuas, and sometimes destroyed by conspecifics.
Movements. Adults and young leave nesting area shortly after young fledge. Some populations remain close to breeding grounds (e.g. Snares, Anvers I). In some places 1st-year birds found near colony. Post-breeding flocks may migrate long distances from S part of range, being absent Apr-Oct. Race *georgiae* common non-breeding visitor to South America; arrives mid-Apr and moults, then leaves mid-Oct. Birds from Antarctica moult on breeding grounds. Race *tristanensis* also winters in South Africa, where *vittata* vagrant. Vagrant to Australia.
Status and Conservation. Not globally threatened. Total population unknown, but must be c. 50,000 pairs, including: 35,000 in South Shetlands, with one colony of c. 9000 pairs at Livingston I; 3000 in South Orkneys; and 2500 on South Georgia. Some archipelagos have tiny populations. Endemic race on Macquarie I, estimated at 40 pairs, must be considered endangered owing to frequent reproductive failures due to human disturbance and domestic and feral cats.
Bibliography. Bailey & Sorensen (1962), Berrutti & Harris (1976), Blake (1977), Brooke (1984a), Chambers (1989), Cooper (1976b), Courtenay-Latimer (1957), Croxall, Prince *et al.* (1984), Dowsett & Forbes-Watson (1993), Escalante (1970c), Favero *et al.* (1991), Garnett (1993), Ginn *et al.* (1989), Johnson (1967), Jouventin (1994), Kaiser (1995, 1996), Liversidge (1957), Mackworth-Praed & Grant (1962), Maclean (1993), Marchant & Higgins (1996), Murphy (1936, 1938), Obst (1985), Parmelee (1988b), Parmelee & Maxson (1975), de la Peña (1992), Rounsevell & Brothers (1984), Sadleir *et al.* (1986), Sagar (1978, 1991), Sagar & Sagar (1989), Sick (1993), Stahl & Weimerskirch (1982), Teague (1955), Urban *et al.* (1986), Watson (1975), Williams *et al.* (1979).

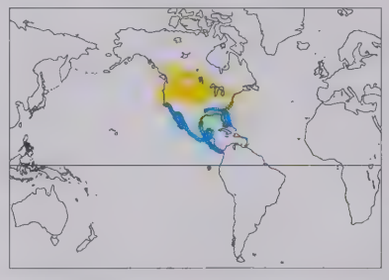
17. Kerguelen Tern

Sterna virgata

French: Sterne de Kerguelen **German**: Kerguelenseeschwalbe **Spanish**: Charrán de las Kerguelen

Taxonomy. *Sterna virgata* Cabanis, 1875, Kerguelen Island.
Some authors have separated Crozet birds as race *mercuri*, based on more restricted grey forehead in non-breeders and subtle soft-part distinctions. Monotypic.

Distribution. S Indian Ocean close to Antarctic Convergence at Kerguelen Is, Prince Edward and Marion Is, and Crozet Is; reported breeding on Heard I erroneous; sympatric with *S. vittata*, but different phenology and feeding niche. Non-breeders remain close to breeding areas throughout year.



Descriptive notes. 33 cm; wingspan 71 cm. Forehead to nape black; upperparts, including uppertail-coverts, smoky grey, with contrasting white rump; outer tail streamers grey, tail greyish; smoky grey below, becoming white on undertail-coverts; white cheek and moustachial area contrasts strongly with grey chin and throat; grey underwing-lining diagnostic, and narrow black trailing edge of primaries; at rest tail does not extend beyond folded wing; bill deep red; feet bright orange (Crozet Is) to dull red (Kerguelen). Separated from *S. vittata* by slightly smaller size, with shorter bill and wings, darker plumage, and grey, rather than white, uppertail and underwing-coverts. Non-breeding adult has bill dull reddish (Crozets) to black (Kerguelen); birds acquire white forehead by Feb, moult beginning during incubation. Juvenile like that of *S. vittata*, finely vermiculated grey, brown and buff, with broad pale and dark bars.
Habitat. Rocky, volcanic islands. Breeds on sparsely vegetated flat ground, either cliff tops or river flats, occasionally close to beach. Non-breeders feed mainly in inshore waters around islands.
Food and Feeding. Fish, crustaceans, molluscs, earthworms, insects and spiders. Diet changes seasonally from mainly crustaceans in Sept, fish in Nov, insects in Dec, to fish in Jan-Feb. In courtship feeding, small fish 50%, crustaceans 14%, insects 36%. Chicks fed mainly on spiders, insects, crustaceans, molluscs and earthworms, at period when *S. vittata* has arrived and is feeding mainly on fish. Feeds alone, or in flocks of up to 20 or more. Fish caught by aerial contact-dipping (83%) and plunge-diving, in inshore waters and around kelp (*Macrocystis*); sometimes walks on kelp to capture invertebrates. Amphipods taken by wading in tide pools. Inland flocks of up to 50 birds feed on insects snatched from vegetation in flight (90%), or by walking. High winds frequently interfere with feeding.
Breeding. Virtually unstudied. Returns to colony in Sept, and begins laying mid-Oct, continuing until Jan; peak breeding early Nov to mid-Dec, 2 months before *S. vittata* nests. Small colonies of up to 30 pairs (mean 8·1), with some solitary pairs, usually more than 200 m from sea. Nests widely scattered; mean nearest-neighbour distance 36 m. Aggressive to intruding skuas. Display repertoire similar to that of *S. hirundo* and *S. vittata*. Nests on moss or grass, assembling stones and twigs, sometimes near high tide line, but often on slopes above beach, occasionally well inland; scrape often lined with plant material. 1 egg on Crozets, 1-2 on Marion, 2 on Kerguelen; incubation 24 days; chick tan with irregular black spots above, buffy below with dark brown chin; brooded for 5 days, then hides in rocks or vegetation near nest; fledging 31-39 days (shorter for earlier chicks), followed by 20 days of dependence. Hatching success in 3 years 73-88%. High mortality of late-hatching chicks through starvation.
Movements. Sedentary. Remains around breeding sites. Movement away from islands not documented.
Status and Conservation. VULNERABLE. One of the most threatened tern species, with no truly secure colony. World population probably not more than 2400 pairs, unless there is an as yet unknown breeding area. About 50 pairs on Prince Edward I, 75 on Marion I, 150-200 in Crozet Is, and up to 2000 in Kerguelen Is. Large population of feral cats on Kerguelen is main potential threat. Salmonid fish introduced into Kerguelen rivers should assist by providing additional food supply. Species requires study and management.
Bibliography. Berruti & Harris (1976), Brooke (1984a), Collar & Andrew (1988), Collar *et al.* (1994), Despin *et al.* (1972), Falla (1937), Jouventin *et al.* (1988), Milon & Jouanin (1953), Murphy (1938), Paulian (1953), Prévost & Mougin (1970), Sagar (1991), Stahl & Weimerskirch (1982), Thomas, T. (1983), Watson (1975), Weimerskirch & Stahl (1988), Weimerskirch *et al.* (1989), Williams *et al.* (1979).

18. Forster's Tern

Sterna forsteri

French: Sterne de Forster **German**: Forsterseeschwalbe **Spanish**: Charrán de Forster

Taxonomy. *Sterna Forsteri* Nuttall, 1834, Saskatchewan River.
Monotypic.
Distribution. British Columbia S to C Californian coast and E to S Ontario, Great Lakes and N Indiana; New York (Long I) to North Carolina; Gulf Coast, from Alabama to Tamaulipas, NE Mexico. Winters from S California to Panama, and from North Carolina to Gulf of Honduras.

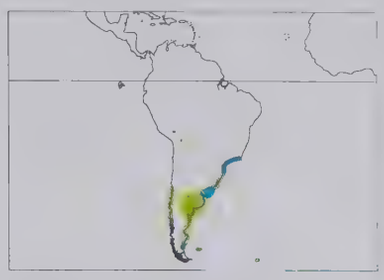
Descriptive notes. 33-36 cm; 127-193 g; wingspan 73-82. Forehead to nape black; upperparts pale grey, underparts white; bill usually distinctly orange-red, not vermilion, and with black tip; legs orange-red; in flight, upper primaries notably pale, silvery-white, contrasting with wing-coverts. Differs from *S. hirundo* in slightly shorter wings and rather paler plumage, especially primaries, which lack dark "wedge" of *S. hirundo*; most easily recognized by its more nasal, lower-pitched calls. Non-breeding adult distinctive: white head and hindneck, with bold black ear patch and dusky nape, and black bill. Juvenile greyish brown, with pale brown markings on back of head, mantle and upperwing-coverts. Head and body moult into 1st-winter plumage Aug-Oct, wing and tail feathers later; appears very similar to non-breeding adult, except for pale grey nape and dark tip to outer tail feathers.
Habitat. Wetlands. Breeds mainly at freshwater lakes, potholes, inland and coastal marshes and salt-pond dykes, rarely on sand, mud or rocky islets. Nests among floating and emergent vegetation, optimal habitat being dense mats at least 5 m across in at least 30 cm of water. Feeds over lakes, streams and estuaries, favouring water less than 1 m deep.
Food and Feeding. Mainly small fish (5-7 cm), also aquatic insects and crustaceans. On Californian coast, mainly shiner perch (*Cymatogaster aggregata*) and northern anchovy (*Engraulis mordax*) up to 10 cm. In South Carolina in winter, mainly menhaden (*Brevoortia tyrannus*) and anchovy (*Stolephorus*). Feeds mainly by plunge-diving or dipping to surface. Sometimes dives from a perch, kingfisher-like, which has twice the energy return of plunge-diving, but is not always an available method. Feeding efficiency enhanced under light wind conditions, rather than dead calm. Sometimes maintains feeding territories.
Breeding. Apr-May on Gulf Coast, to late May elsewhere. Forms loose colonies of 5-250 pairs, rarely more; sometimes solitary. Fairly high turnover rates. Nest a depression in floating vegetation; 98% of

nests on large muskrat (*Ondatra zibethica*) lodges where these are available; also on boards, infrequently (but increasingly) on dredge spoil, sand or fine shell, and occasionally on coarse gravel islands (Washington). May assemble a nest of grass and sedge or horsetail on dry mud or grassy hummocks; uses higher, dryer and larger sites than *Chlidonias niger* in same marsh; in salt-marshes relies mainly on wrack, building taller nests on lower sites than *S. hirundo*, but re-laying sooner, with larger clutches and higher hatching success, if initial nest flooded. Nests sometimes widely spaced, depending on available surfaces; usually 3-20 m apart, but on muskrat houses as close as 20 cm and on salt-marsh 50 cm apart. Adults recognize nest-site rather than eggs. Mean clutch size 2·8; incubation 23-26 days; chick similar to that of *S. hirundo*, but with darker, more discrete black spots. Nest losses due mainly to flooding, and to mink (*Mustela vison*) predation, muskrat activity, and spawning carp (*Carassius*); 12-36% of nests successful in one study. Aggressive reactions of Yellow-headed Blackbirds (*Xanthocephalus xanthocephalus*) help terns deter predators. Productivity very variable, from total failure to c. 1·4 young/nest. In one study, 58% of chicks survived at least 5 days. Colonies on Great Lakes have much lower hatching success, negligible productivity, and more developmental defects than nearby inland colonies.

Movements. Following northward post-breeding dispersal, migrates S. Birds breeding on Pacific coast winter from S California to Costa Rica and Panama. Great Plains birds migrate mainly overland, and winter mostly on Gulf Coast. Atlantic coast breeders winter from S Virginia to Costa Rica and in Caribbean; occasionally found N to New England in winter.

Status and Conservation. Not globally threatened. USA population exceeds 14,000 pairs, but numbers in Canada and Mexico not known. Atlantic coast population totals c. 6000 pairs; Gulf Coast population centred on Louisiana, where colonies of nearly 3000 pairs have been found; W and Great Plains population has not been censused. Species has extended range northwards in recent decades: in 1950's, bred N only to Virginia, but is now an uncommon breeder in a few colonies in S New Jersey, and a marginal breeder in New York, where first recorded nesting in 1981. In Great Lakes, number of nests at L St Clair and L Huron increased in early 1980's from 100 to 850. With loss of coastal marsh habitat, some birds have shifted to dredge-spoil islands. Reproductive failure in Great Lakes attributed in part to contamination by PCB's (see page 643).

Bibliography. Baltz *et al.* (1979), Bent (1921), Bergman *et al.* (1970), Blake (1977), Blokpoel & Scharf (1991b), Buckley & Buckley (1984b), Cave (1982), Clapp & Buckley (1984), Cramp (1985), Fox *et al.* (1991), Goossen *et al.* (1982), Hall (1988, 1989), Hall & Miller (1991), Harrison (1984a), Howell & Webb (1995a), Kubiak *et al.* (1989), Martin & Zwank (1986), McNicholl (1979, 1981, 1982, 1983), Monroe (1968), Neuchterlein (1981), Ohlendorf *et al.* (1988), Olsen & Larssen (1995b), Portnoy (1977), Reed (1985), Reed & Ha (1983), Reed *et al.* (1982), Richards (1990), Ridgely & Gwynne (1989), Root (1988), Salt & Willard (1971), Scharf & Shugart (1984), Schwartz & Satlling (1991), Stiles & Skutch (1989), Storey (1987b).



19. Trudeau's Tern

Sterna trudeaui

French: Sterne de Trudeau **German**: Weißscheitel-Seeschwalbe **Spanish**: Charrán Coroniblanco
Other common names: Snowy-crowned Tern

Taxonomy. *Sterna Trudeaui* Audubon, 1838, Great Egg Harbor, New Jersey (probably in error). Monotypic.

Distribution. Coast and interior of South America, breeding from SE Brazil and Uruguay to Patagonia, rarely to Santa Cruz, and in Chile (Aconcagua to Llanquihue).

Descriptive notes. 35 cm; 146-160 g; wingspan 76-78 cm. Head and upper neck white, with black spot in front of eye and dark band behind; upperparts and upperwings pale grey, with whitish rump and uppertail-coverts; underparts greyish white; iris dark brown; bill yellow, with broad subterminal black band; feet reddish orange. Like non-breeding *S. forsteri*, but latter has all black bill and dusky nape. Non-breeding adult similar, but with stripe on side of head greyer. Juvenile has back and scapulars patterned with dark and white markings, dark carpal bar, tail feathers with dark subterminal mark, bill black, and legs dark with yellowish webs. Immature creamy white.

Habitat. Fresh and saline wetlands, both inland and coastal. Breeds on vegetated lagoons of *pampas* and Patagonia, mainly in marshes, but also on dykes and islands in saline lagoons. Feeds at wetland edges, and also over fields.

Food and Feeding. Small fish and insects. In Chile, feeds mainly on pejerrey (*Austromenidia laticlavia*). Forages over shallow clear water on edges of lagoons, rivers and estuaries, but also over ploughed fields. Plunge-dives for fish.

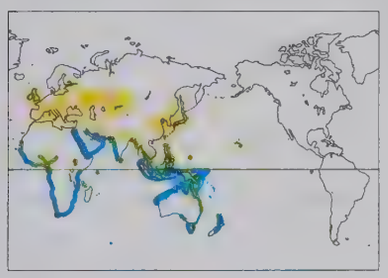
Breeding. Virtually no data published. Recorded Oct in N, Nov in Buenos Aires, Dec in Chubut. One colony in a lagoon held 30-40 nests. Often nests with Brown-hooded Gulls (*Larus maculipennis*), in densely vegetated marshes. Builds floating platform of plant stems, free or anchored to emergent vegetation, in water 10-150 cm deep. 3 eggs (2-4); adults vigorously attack and even strike intruders. Productivity not studied, but one report of 55 adults accompanied by 37 juveniles in Dec.

Movements. Outside breeding season, ranges N on Pacific coast to S Peru, and on Atlantic coast to Rio de Janeiro region. Some linger as far S as Chubut into Jul. Accidental in Straits of Magellan. Considered abundant on coast of Uruguay and at mouth of R de la Plata in Mar; numerous on Buenos Aires *pampas* in Sept-Feb, but less common during austral winter.

Status and Conservation. Not globally threatened. Status not well known, and no trends documented. In Brazil no colonies known, although breeding activities observed in Rio Grande do Sul, and species common in lagoons along coast. Does not nest on small lakes, so maintenance of largest freshwater wetlands essential. Loss of wetland habitat and lack of protection of existing wetlands are potential major problems. In Chile, uncommon from Aconcagua to Llanquihue.

Bibliography. Antas (1991), Belton (1984), Blake (1977), Canevari *et al.* (1991), Clark (1986), Contreras *et al.* (1990), Donahue & Petersen (1980), Escalante (1970c, 1991), Gibson (1920), Hellmayr & Conover (1948), Johnson (1967), Klimaitis & Moschione (1987), Meyer de Schauensee (1982), Murphy (1936), Narosky & Yzurieta (1987), Olmos *et al.* (1995), Olrog (1984), de la Peña (1992), Pinto (1964), Sick (1985c, 1993), Teague (1955), Vooren & Chiaradia (1990).

PLATE 56



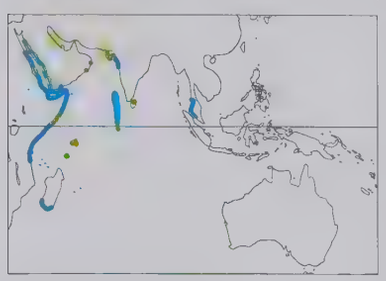
inches 6
cm 15

20. Little Tern

Sterna albifrons

French: Sterne naine **German**: Zwergseeschwalbe **Spanish**: Charrancito Común

Taxonomy. *Sterna albifrons* Pallas, 1764, Netherlands.
Forms nearly cosmopolitan superspecies with *S. saundersi*, *S. antillarum*, *S. superciliaris*, *S. lorata* and probably also *S. balaenarum*, all of which formerly placed in separate genus *Sternula*. Some works treat *S. antillarum*, and sometimes *S. saundersi*, as conspecific with *S. albifrons*. Validity of races *innominata* and *placens* questionable. Apparent hybridization with *S. nereis* in S Australia indicates close relationship; long-term study of relationships required. Six subspecies recognized.
Subspecies and Distribution.
S. a. albifrons Pallas, 1764 - Europe through W Asia E to Nepal, and presumably this race also in Kenya (breeding at L Turkana), and in W Indian Ocean (Seychelles and Comoro Is, where resident, but breeding not confirmed); winters on coasts from Africa E to W India.
S. a. guineae Bannerman, 1931 - Ghana to Gabon, with marginal population in Mauritania and Senegal which may be this race or nominate.
S. a. innominata Zarudny & Loudon, 1902 - islands in Persian Gulf.
S. a. pusilla Temminck, 1840 - NE India and Myanmar, islands off Sumatra and Java, and probably this race in Sri Lanka.
S. a. sinensis Gmelin, 1789 - SE Russia, China, Japan, SE Asia, Philippines and New Guinea; recent colonist to Micronesia (Saipan) E to Hawaii most likely this race, and possibly also some birds in Australia, New Britain and nearby waters; N populations mostly winter in Malaysia.
S. a. placens Gould, 1871 - E Australia and E Tasmania.



Descriptive notes. 22-28 cm; 47-63 g (average 50 g, Ukraine); wingspan 47-55 cm. Archetypical small tern: small, with white forehead, black cap and lores, grey back and wings, white rump, and white underparts; bill bright yellow with small dark tip; legs and feet orange-yellow to yellow. Differs from *S. saundersi* in white of forehead reaching behind eye, less black on primaries, and usually brighter yellow legs. Separated from *S. nereis* mainly by black, not white, lores (black from eye to bill base), and by black tip to bill; apparent hybrids have black on lores reaching almost to bill, and very small black bill tip. Non-breeding adult has pale-streaked forecrown, white lores with black spot before eye, dark lesser coverts, and blackish bill and legs. Juvenile has black chevrons on mantle; paler secondaries and inner primaries contrast with darker wing-coverts and outer primaries. 1st-winter plumage acquired Oct, when similar to non-breeding adult. Races differ little; shafts of outer 3 primaries dark brown to brownish white in nominate, but white in *pusilla* and *sinensis*.
Habitat. Subtropical to temperate regions, reaching altitude of 2000 m in Armenia. Continental populations mainly coastal, but also inland along rivers; also on oceanic islands. Breeds on barren or sparsely vegetated sandy, shell, rocky and coral islands, shingle beaches, spits in estuaries and lakes, salt-marshes, salt-pans and rivers, and on reefs. Occasionally in grassy areas or on bare mud. Outside breeding season, frequents tidal creeks, coastal lagoons and salt-pans; sometimes feeds far out to sea.
Food and Feeding. Mainly small fish and crustaceans (3-6 cm), also insects, annelids and molluscs. Main fish sandeels (*Ammodytes*), roach (*Rutilus rutilus*), rudd (*Scardinius erythrophthalmus*), carp (*Cyprinus carpio*), perch (*Perca fluviatilis*). Insects mainly Orthoptera, Odonata, Diptera, Coleoptera. In Crimea 91% of birds had eaten fish, but in neighbouring Sivash (Ukraine) 99% had eaten insects and only 54% fish. Some studies show 90% crustaceans brought to young (S England). Forages by quartering back and forth over water; specializes in prolonged hovering and plunge-diving into shallow water, often at edge of advancing tide. Groups of birds may dive synchronously. Takes insects from vegetation and water surface by aerial-dipping. Also hawks for small flying insects over water. In Italy, most birds foraged within 3 km of colony.
Breeding. Apr in W Africa, May-Jun in Europe and India, May-Aug in Sri Lanka. Usually in small to medium-sized colonies; 42% of 1-5 pairs, only 5% of 40+ pairs; rarely over 100 pairs. Forms synchronous subcolonies, usually monospecific. Vegetation cover usually less than 15%, though occasionally nests in shelter of bushes; sometimes on floating objects, e.g. buoys, abandoned concrete structures, also on roofs in some areas. Nest usually bare, but in marshes builds on platforms of shell or vegetation. Distance between nests usually over 2 m, often much more, but sometimes only 0·6-1 m. Clutch 2-3 eggs (1-4); incubation 21-24 days; chick creamy-grey or white with sparse or dense black spots; hatching weight 6·5 g; reported to recognize parents' voices on day 1; up to 63 feeds/day recorded: fledging 20-24 days. Average age of first breeding 3 years, occasionally 2. Recorded longevity of 21 years.
Movements. N breeders migrate S from late Aug. Those from W & C Europe spend Nov-Mar on African coasts, mainly in Gulf of Guinea area, but ranging to South Africa and even Kenya. Birds from E Europe and SW Asia migrate to Red Sea and Arabian Sea to E Africa, thousands congregating on passage in inlets in SW Caspian Sea when fish fry abundant. Breeders from Caspian Sea region move to Persian Gulf and W India, while E Asian birds migrate S to SE Asia and winter in the seas of Malaysia to Philippines. Some of those nesting in Australia winter in waters around Indonesia and New Guinea.
Status and Conservation. Not globally threatened. World population c. 70,000-100,000 pairs, but many local populations declining. In former USSR c. 50,000, increasing in E but decreasing in W; in Europe c. 11,000 and decreasing, with large numbers in Italy and Netherlands, and estimated c. 5500-6000 pairs in Spain and 2430 pairs in Britain; few 100's of pairs in W Africa (Mauritania, Senegal); 800-1150 pairs in Iran. Faces many adversities: many coastal beaches have been developed, and mainland breeding sites vulnerable to human disturbance, rats and cats; direct damage and disturbance by humans are main factors accounting for recorded decline. Human intrusion, including birdwatchers, causes nest failures. Many predators in colonies, especially various gulls, corvids, and even *S. hirundo*. Marked declines in Britain and W Europe due to human impact on beaches; range contracting in C Europe, but less change in Scandinavia. In Italy 20% of colonies have suffered human disturbance, and in Crimea many nests lost to destructive children, cattle and gulls. Some apparent range extensions: colonized South Australia in late 1960's; in 1988, discovered nesting in Saipan and Hawaii.

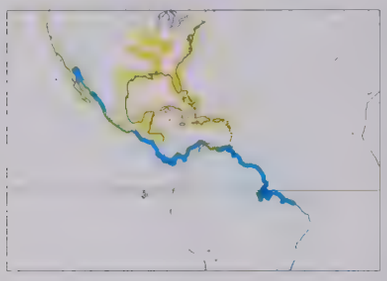
21. Saunders's Tern

Sterna saundersi

French: Sterne de Saunders **German**: Orientseeschwalbe **Spanish**: Charrancito de Saunders
Other common names: Black-shafted Tern

Taxonomy. *Sterna Saundersi* Hume, 1877, Karachi. Forms a superspecies with *S. albifrons*, *S. antillarum*, *S. superciliaris* and *S. lorata*. Sometimes considered conspecific with *S. albifrons*. Monotypic.
Distribution. Breeds in Red Sea (N to at least Yanbu) S to Socotra and S Somalia and off Saudi Arabia and Oman, along coasts of Persian Gulf and locally E to NW India; Sri Lanka, mainly in NW & E; large numbers throughout year at Addu Atoll (Maldives), where probably breeds in Apr with other terns, and probably also on Amirantes and possibly Seychelles. Winters from Red Sea S to Tanzania and Madagascar and E to India, and probably in Seychelles and off Malaysian Peninsula.

Descriptive notes. 20-28 cm; 40-45 g; wingspan 50-55 cm. Extremely similar to *S. albifrons*, from which distinguished by: straight upper border to white forehead (white does not reach behind eye); slightly paler grey upperparts, contrasting more with blackish outer primaries; grey rump same colour as mantle, whereas usually much paler in *S. albifrons*; legs and feet dusky yellow-olive, rather than orange-yellow; 3-4 outer primaries black, with black shafts, whereas *S. albifrons* usually has only 2 outer primaries dark, brownish to grey-black, with 2-3 brownish shafts. Non-breeding adult darker above, often darker than *S. albifrons*, otherwise very similar. Juvenile virtually identical to that of *S. albifrons*, but may have darker bar on secondaries.
Habitat. Coasts, estuaries, and tidal lagoons; rare inland.
Food and Feeding. Small fish, crustaceans and molluscs; also various insects. Feeds mainly by plunge-diving, often preceded by long bouts of hovering.
Breeding. Very few data available. Season May in Karachi and Sri Lanka. Forms small, sparse colonies; nests 20-100 m apart. Nest-site above high tide line, or on mudflats; prefers small mounds of wind-blown sand around a plant or other object. Nest is a hollow or an animal footprint, bare or lined with shall fragments and small pebbles. Lays 2 pale eggs. No further information available.
Movements. Movements not well understood. Non-breeders seen in Red Sea N to Gulf of Aqaba, and S along E African coast to N Tanzania, as well as Madagascar and along W coast of India, in Gujarat, Bombay, also Laccadives and Maldives; probably this species also in Seychelles. Uncommon to very rare non-breeding visitor to S Thailand, Malay Peninsula and Straits of Malacca. Research needed.
Status and Conservation. Not globally threatened. Not at all well known: population figures unknown, and even colony inventory not available; Iran thought to hold 130-150 pairs. Species probably frequently overlooked, due to considerable difficulties in identification. Stated to be abundant in Karachi area. Colonies vulnerable to most of same adversities as those facing *S. albifrons*.
Bibliography. Ali & Ripley (1982), Ash & Miskell (1983), Beaman (1994), Bregnballe *et al.* (1990), Chandler & Wilds (1994), Cramp (1985), Dowsett & Dowsett-Lemaire (1993), Dowsett & Forbes-Watson (1993), Evans (1994), Feare (1979a), Gallagher *et al.* (1984), Goodman *et al.* (1989), Harrison (1983b), Hüe & Étchécopar (1970), Langrand (1990), Mackworth-Praed & Grant (1957), Medway & Wells (1976), Milon *et al.* (1973), Olsen & Larssen (1995a, 1995b), Perennou *et al.* (1994), Phillips (1978), Rands *et al.* (1987), Richards (1990), Ripley (1982), Roberts, T.J. (1991), Shirihai (1996), Short *et al.* (1990), Smythies (1986), Ticehurst (1924), Urban *et al.* (1986).



22. Least Tern

Sterna antillarum

French: Petite Sterne **German**: Amerikanische Zwergseeschwalbe **Spanish**: Charrancito Americano

Taxonomy. *Sternula antillarum* Lesson, 1847, Guadeloupe, Lesser Antilles.
Forms superspecies with *S. albifrons*, *S. saundersi*, *S. superciliaris* and *S. lorata*. Long considered a race of *S. albifrons*, but recently separated mainly on basis of voice. Currently accepted polytypic arrangement disputed by findings of morphometric and biochemical analyses. Proposed form *mexicana* for birds of Pacific coast of Mexico is not separable. Three subspecies recognized.
Subspecies and Distribution.
S. a. browni Mearns, 1916 - C California (San Francisco Bay) to Baja California and W Mexico; winters mostly in Central America.
S. a. athalassos Burleigh & Lowery, 1942 - inland rivers in C North America, from N Great Plains to N Louisiana and Texas; winters to N Brazil.
S. a. antillarum (Lesson, 1847) - Bermuda, and Maine S to Texas (including lower Rio Grande Valley) and Honduras, and on through Caribbean to N Venezuela; winters to N Brazil.
Descriptive notes. 22-24 cm; 39-52 g (New York 44-52 g, average 47·4 g); wingspan 51 cm. Very similar to *S. albifrons*, with white forehead, black cap, grey upperparts and white underparts; differs marginally in greyer rump and tail, and more clearly inflected disyllabic contact call. Bill bright yellow with black tip; legs yellow to orange, sometimes with greyish or pinkish tinge. Non-breeding adult and juvenile much as *S. albifrons*, but adult has grey rump and tail, and juvenile has stronger brown scaling

On following pages: 23. Yellow-billed Tern (*Sterna superciliaris*); 24. Peruvian Tern (*Sterna lorata*); 25. Fairy Tern (*Sterna nereis*); 26. Damara Tern (*Sterna balaenarum*); 27. White-cheeked Tern (*Sterna repressa*); 28. Black-bellied Tern (*Sterna acuticauda*); 29. Aleutian Tern (*Sterna aleutica*); 30. Grey-backed Tern (*Sterna lunata*); 31. Bridled Tern (*Sterna anaethetus*); 32. Sooty Tern (*Sterna fuscata*); 33. Black-fronted Tern (*Sterna albostriata*).

on upperparts and bolder lesser-covert bar. 1st-summer birds have conspicuous dark carpal bar, and either black bill, white forecrown and black eyestripe and nape ("*portlandica*"), or yellowish bill and white flecking on blackish crown ("*pikei*"). Races poorly differentiated: *browni* deeper grey above, greyish white below, and frequently lacks black tip to bill.

Habitat. Lakes, rivers and estuaries; Californian and E populations generally strictly coastal, though some nest inland in Florida. Breeds on barren or sparsely vegetated sandy beaches or islands, gravel, sand or shell bars, dry mudflats, dredge-spoil islands, dykes, parking lots; also roof tops, now predominant site in Florida; more recently, in sandpits inland. Forages over quiet waters of lagoons, marshes and estuaries; occasionally beyond surf zone.

Food and Feeding. Small fish fry on breeding grounds. Also shrimps, marine worms, and occasionally flying ants and other insects. Feeds mainly by plunge-diving from up to 10 m, often preceded by prolonged hovering. Occasionally performs surface-dipping and aerial hawking. Often feeds within few hundred metres of colony.

Breeding. Apr in Florida and Texas, May in West Indies and California, May-Jun in NE USA, May-Jul in S Caribbean; mid-Jun in interior (when floodwaters recede). Usually in monospecific colony or subcolony of 5-200 pairs, but up to 1500 on Long I and 3000+ in Mississippi. Nests 3-20 m apart, occasionally less than 1 m; in interior often more than 100+ m, or even solitary. Prefers sand mixed with shell or gravel, and slightly elevated ridges; on vegetated beaches nests further from vegetation than random, but converse true when cover less than 5%. Slight scrape, often in bare sand, occasionally near object such as a shell, rock or stick. Clutch 1-3 eggs, (1-3), usually 2 in tropics; average 1·6-2·2 in New York, 2·1-2·5 in Mississippi and interior USA, 1·7-2·2 in California, 1·6 in Cuba. Incubation 19-24 days (report of 14-16 days erroneous), eggs unattended 11% of time in undisturbed colonies; chick greyish white or buffy (66% buffy, Mississippi), and immaculate (less than 15%, New York; 37%, Mississippi) to heavily spotted; fledging 17-21 days. Productivity very variable, 0·2-1·5 per pair; many total failures through flooding. Average adult annual survival 85-92%; adults have c. 9·5 breeding seasons. First breeding at 2 or 3 years. Longevity 21 years.

Movements. Highly migratory. Pacific breeders arrive late Apr, and return in Aug to coasts of W Mexico and Central America. Interior and E birds migrate to Caribbean and N South America, wintering mainly off Brazil. Substantial inter-colony exchange from year to year, even when original colony persists. Nominate race accidental inland.

Status and Conservation. Not globally threatened. All races vulnerable. Due to taxonomic split from *S. albifrons*, status should be re-examined. Race *browni* (800 pairs, 1994) and *athalassos* (under 1000 pairs) considered endangered. Nominate *antillarum* population in E USA estimated at 21,500 pairs in 300 colonies, with 3000-3600 pairs on Long I (New York) in mid-1980's; but has declined greatly in many areas owing to beach development and severe recreational pressure; intensive protection and management have stabilized some populations. Vulnerable to disturbance by trapping (for ringing and patagial tagging). Many avian and mammalian predators documented; ants and ghost crabs (*Ocypode quadrata*) kill chicks, and Fish Crows (*Corvus ossifragus*) eliminate all chicks in some colonies. Mississippi coastal population thriving, however, since mid-1970's, with up to 7000 pairs. Many natural habitats are being lost, while in Florida changing roof surfaces from gravel to plastic threatens established colonies. Decoys effective in attracting adults to protected beaches. Chick-shelters both protect against and facilitate predation, and must be studied at each colony prior to use. Intensive site-protection, management and wardening has increased New Jersey population. Interior population has suffered habitat loss through managed water levels connecting islands to mainland, or through flooding; many sandbars degraded, but birds now shifting to sandpits when available; current productivity in Mississippi River Valley sufficient to maintain population. Protection of habitat essential.

23. Yellow-billed Tern

Sterna superciliaris

French: Sterne argentée **German**: Amazonasseeschwalbe **Spanish**: Charrancito Amazónico
Other common names: Amazon Tern

Taxonomy. *Sterna superciliaris* Vieillot, 1819, Paraguay.
Forms superspecies with *S. albifrons*, *S. saundersi*, *S. antillarum* and *S. lorata*. Monotypic.
Distribution. E Colombia E to the Guianas and S to NE Peru and on to C Argentina (Buenos Aires).
Descriptive notes. 23 cm; 40-57 g. Very similar to *S. antillarum*, but with stouter, entirely yellow bill, lacking dark tip. Subadult has yellowish bill with dark horn-brown tip, and greyish crown with black streaks, whereas subadult *S. antillarum* usually has wholly black bill and conspicuous blackish carpal band. Juvenile has ochraceous forehead, lores and crown, with dark streaking and dark auricular area; upperparts greyish, with pale buffy markings, and with dark subterminal marks on each feather; dark carpal bar.
Habitat. Broad rivers. Breeds mainly on riverine sandbars and lake beaches, in mixed colonies with Black Skimmers (*Rynchops niger*) and *Phaetusa simplex*; more restricted to large rivers than *Phaetusa*; feeds mainly over shallow shoals on large rivers, often concentrating at tributary mouths. In Brazil, breeds mainly along inland rivers and lakes, sparingly at river mouths on coast; in Argentina along R Uruguay, R Paraná and R Pilcomayo to NE Buenos Aires; in Uruguay commonly on lakes and rivers, uncommonly along coast. Non-breeders mainly on coast and estuaries, also various water bodies, from rice fields to brackish lagoons.

Food and Feeding. Small fish (7-45 mm), shrimps and insects; sometimes predominantly insects (Peru). Often feeds by hovering and plunge-diving from 3-8 m into shallow water, usually close to shore. Usually feeds alone.
Breeding. Virtually unstudied. Nov in Surinam, Dec in Uruguay, Jul in Peru; timing dependent on exposure of riverine sandbars in dry season. Colonies of up to 20 pairs, more often 3-10; nests widely spaced, often more than 50 m apart, frequently solitary. 2-3 eggs, average 1·94. Productivity 1·04/nest; flooding is main cause of egg loss.
Movements. Unknown. Main movement is apparently along river valleys to coasts, where non-breeders congregate.
Status and Conservation. Not globally threatened. No population figures available, and status and trends virtually unknown. Main threats are flooding and human disturbance, latter significant on some beaches.

Bibliography. Antas (1991), Belton (1984), Blake (1977), Canevari *et al.* (1991), Contreras *et al.* (1990), Davis (1935), Escalante (1970b, 1970c, 1991), Groom (1992), Haverschmidt (1968, 1972a), Haverschmidt & Mees (1995), Hayes (1995), Hellmayr & Conover (1948), Herklots (1961), Hilty & Brown (1986), Klimaitis & Moschione (1984), Krannitz (1989), Meyer de Schauensee & Phelps (1978), Murphy (1936), Olmos *et al.* (1995), de la Peña (1992), Preston (1962), Remsen (1990), Ridgely & Gwynne (1989), Sick (1985c, 1993), Snyder (1966), Teague (1955), Tostain *et al.* (1992), Vooren & Chiaradia (1990), Willard (1985).

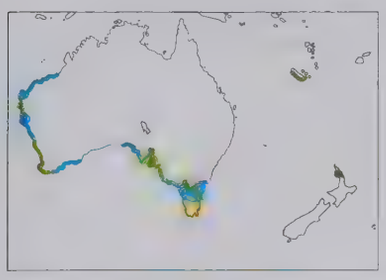
24. Peruvian Tern

Sterna lorata

French: Sterne du Pérou **German**: Peruseeschwalbe **Spanish**: Charrancito Peruano

Taxonomy. *Sterna lorata* Philippi and Landbeck, 1861, Arica, Chile.
Forms superspecies with *S. albifrons*, *S. saundersi*, *S. antillarum* and *S. superciliaris*. Monotypic.
Distribution. Humboldt Current zone, from C Ecuador (Guayaquil) to N Chile (Tarapacá).

Descriptive notes. 22-24 cm. Typical small tern: white forehead extending over eye, contrasting with black cap and lores; pale grey upperparts; dark outer primaries; pale greyish white sides of neck and underparts; yellow bill tipped black, dark yellow legs. Non-breeding adult has crown streaked with white. Juvenile has broad dark brown face mask from lores to ear-coverts; buffy underparts; beige upperparts with bold black chevrons on lesser coverts, less pronounced on greater coverts; blackish primaries; dark-tipped flesh-coloured bill and flesh-coloured legs.
Habitat. Coastal. Breeds on broad sandy beaches and sand dunes, often more than 1000 m from tide-line; and on barren stony desert several kilometres inland.
Food and Feeding. Mainly small fish, particularly anchovetta (*Engraulis ringens*); c. 10% of diet is krill (*Euphausia*). Feeding methods similar to those of allospecies.
Breeding. Oct-Jan (mainly Nov); full-grown juveniles in mid-Feb. Semi-colonial to solitary; nests more than 50 m apart in sparse colonies of 2-15 pairs on back beaches and on desert plains. Scrape on unvegetated flats, usually near some object such as stone, shell, bone, stick. 1-2 eggs; incubation 22-23 days; chick pale grey, finely spotted black on head and back; hatching weight 6-7 g. Many eggs disappear; usually only 1 chick raised. May skip nesting in El Niño years.
Movements. Unknown, but returns to colony sites in mid-Oct.
Status and Conservation. Not globally threatened. Status very poorly known; species probably rather rare. Estimated maximum population in Peru 5000 pairs. Potential predators include Peregrine Falcon (*Falco peregrinus*), grey fox (*Dusicyon culpaeus*), and skunk (*Conepaetus rex*). Vulnerable to egg loss. Unattended nests may quickly be buried by sand.



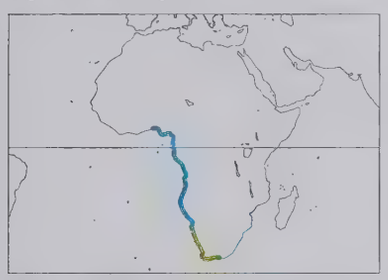
Bibliography. Blake (1977), Devillers & Terschuren (1976b), Duffy & Hurtado (1984), Duffy *et al.* (1984), Hellmayr & Conover (1948), Johnson (1967), Koepcke (1970), Meyer de Schauensee (1982), Minaya (1968), Murphy (1936), Parker *et al.* (1982).

25. Fairy Tern

Sterna nereis

French: Sterne néréis **German**: Australseeschwalbe **Spanish**: Charrancito Australiano
Other common names: Nereis/Australian Fairy Tern

Taxonomy. *Sternula nereis* Gould, 1843, Bass Strait.
Overlaps in SE Australia with *S. albifrons*, and occasionally hybridizes. Four subspecies recognized.
Subspecies and Distribution.
S. n. horni Mathews, 1912 - Western Australia.
S. n. nereis (Gould, 1843) - South Australia, Victoria and Tasmania.
S. n. exsul (Mathews, 1912) - New Caledonia.
S. n. davisae (Mathews & Iredale, 1913) - N North I, New Zealand.
Descriptive notes. 22-27 cm; 57 g; wingspan 45-51 cm. Forehead and lores white, white not extending behind eye; crown and nape black, extending just forward of eye as dark spot on rear lores; upperparts and upperwing pale grey, rump paler than back; forked tail pale grey, with inner feathers white; neck and underparts whitish; bill bright yellow, usually without black tip; legs orange to orange-yellow. Very like *S. albifrons*, but latter has black tip to yellower bill, and black lores. Non-breeding adult has white extending as streaks over crown, and broad black band across nape from eye to eye; lacks dark carpal bar of *S. albifrons*, and has less contrasting primaries; bill has black tip, and often small black basal region. Subadult has wing-coverts grey-brown, and bill and legs dark brownish or black.
Habitat. Coasts, occasionally inland. Breeds on sandy or coral islands and extensive coastal dunes. Forages mainly in bays and estuaries, occasionally beyond surf.
Food and Feeding. Mainly small fish, also gastropods and crustaceans. Chicks seen to eat plant matter and small arthropods in seaweed. Feeds in shallow water by plunge-diving, or hovering and contact-dipping.
Breeding. Early Sept in N to late Sept in S; from mid-Nov in New Zealand. Colonial in Australia; often solitary or widely spaced in New Zealand, nests sometimes 20 m apart, usually further. In SE Australia sometimes in *S. albifrons* colonies, occasionally interbreeding. Prefers raised ridges or mounds.



Nest a hollow in sand or shell, sometimes surrounded by shells on barren beach or spit. 1-2 eggs, with 20% 1 egg, average in New Zealand 1·77; incubation 20-25 days; adults leave early when intruders approach (small New Zealand colonies), or vigorously mob (large Australian colonies); chick very pale buff-white with very faint black dots or grey streaking, pinkish bill and legs; remains by nest for several days; fledging 22-23 days; dependent up to 50 days. Productivity in protected New Zealand colonies averaged 0·7 young/pair.
Movements. Tasmanian breeders and some from S Australia migrate N. Some from W Australia sedentary, others move N to NW Australia. New Zealand birds leave colony site, returning in Aug.
Status and Conservation. VULNERABLE. Australian population currently estimated at no more than c. 2000 pairs. New Zealand race *davisae* endangered; formerly common on both islands, but now confined to N North I, where only 4 pairs in 1983, when protection began; increased to 10 breeding pairs in 1994; main threats are human disturbance and intrusion, to which breeding birds are very vulnerable, and predation by rats and cats. Formerly common in Western Australia, where flocks of up to 15,000 birds recorded, but population greatly reduced; in Victoria, many colonies lost as offshore islands have become more accessible to humans; may also suffer from competition with *S. albifrons*, which is extending its range. Status of New Caledonian race *exsul* unknown. In all areas, nests are lost through flooding.
Bibliography. 26. **Damara Tern**

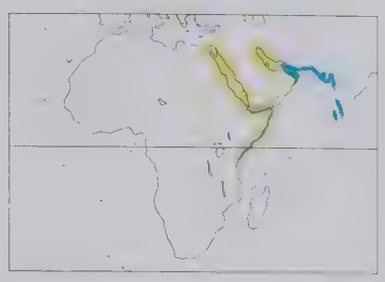
Sterna balaenarum

French: Sterne des baleiniers **German**: Damaraseeschwalbe **Spanish**: Charrancito de Damara

Taxonomy. *Sternula balænarum* Strickland, 1852, Damaraland.
Sometimes included in *S. albifrons* superspecies. Monotypic.
Distribution. Namibia to Cape Province; recorded N to Cabinda (N Angola) during breeding season. Migrates as far as Nigeria.



Descriptive notes. 23 cm; 46 g; wingspan 51 cm. Typical small tern, but all black bill, black forehead and lores; legs yellowish to dusky. Non-breeding adult has white forehead, and crown mottled grey and blackish. Juvenile has buffy crown, dark band through eye and across nape, grey flight-feathers, and brown wing-coverts with dark edging. 1st-winter as non-breeding adult, but darker primaries and faint carpal bar.
Habitat. Breeds on gravel and stony plains and dunes, up to 3 km inland; shuns outer beach frequented by predators. Feeds in inshore waters of bays, estuaries, lagoons and salt-pans, and in surf zone.
Food and Feeding. Mainly small fish, including mullet (*Mugil richardsonii*) and anchovy (*Engraulis japonica*), as well as small squid. Chicks fed fish 1·5-12 cm long, and up to 30 g. Forages by hovering followed by plunge-diving.
Breeding. Late Oct to mid-Nov, with new clutches into Feb. Groups of 1-10 pairs, occasionally 50; nests widely spaced, average distance 57-185 m; no territorial interactions observed. Prefers unvegetated troughs between dunes, with scattered shells and stones; often only 1 pair per trough. Barely visible scrape, with few pieces of shell or none. 1 egg, very rarely 2; adults weakly mob intruders; incubation 18-22 days; chick white below, fawn above finely speckled with black, matching lichen-flecked rocks; leaves nest at 2 days, crouches motionless among gravel; fledging 20 days; dependent for 2·5 months after fledging. Productivity 0·16-0·35 young/pair.
Movements. Disperses N after breeding season, reaching as far N as Nigeria, where present at Lagos Apr-Jan and most numerous Jul-Oct.
Status and Conservation. Not globally threatened. Currently considered near-threatened. Estimated population 1000-2000 pairs in 1982, but recent observations of 5000 in NW Namibia result in minimum total population of 5755 individuals. Although species is protected by ordinances in both Namibia and South Africa, its breeding areas are not protected. Restricted access to c. 1000 km of Diamond Coast between Swakopmund and Oranjemund incidentally protects some breeding habitat from human disturbance, but only a few pairs known to nest in that area; mining development near breeding areas may threaten even these. Off-road vehicles threaten colonies; land reclamation, dredging and hotel construction impact on feeding areas. Direct effect of human disturbance unknown, but has caused some nests to be abandoned. Nesting in widely scattered, loose colonies, far behind outer beaches, helps to reduce predation risk, particularly from black-backed jackal (*Canis mesomelas*).

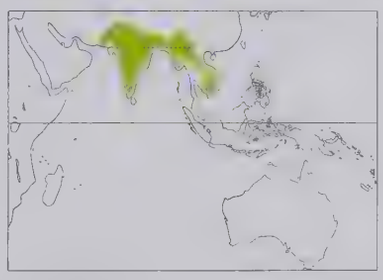
27. **White-cheeked Tern**

Sterna repressa

French: Sterne à joues blanches **German**: Weißwangen-Seeschwalbe **Spanish**: Charrán Arábigo

Taxonomy. *Sterna repressa* Hartert, 1916, Al Faw, south Iraq, Persian Gulf. Monotypic.
Distribution. Red Sea S to Somalia and Kenya, and E through Persian Gulf and Oman to W India (Bombay). Winters on coasts of NE Africa and Arabian Sea to SW India and Laccadives.
Descriptive notes. 32-35 cm; 113-142 g; wingspan 73-83 cm. Darker than all other typical *Sterna* terns, in breeding plumage recalling *Chlidonias hybridus*: black forehead to nape, with white cheeks set off by ash grey underparts; dark ashy grey above, including upperwing, rump and tail; bill dark red



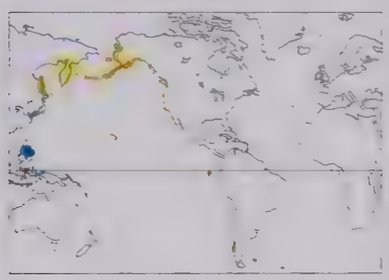
at base with black tip, but variable, and sometimes all black; legs bright red to dark brownish red. Very similar to *S. hirundo* and *S. paradisaea*, especially in winter, but smaller, with shorter wings and legs, and chunkier appearance in flight. Non-breeding adult has head white, with black or dark brown areas around eye, and from ear-coverts across nape, with pale nuchal collar; often shows patchy grey and white underparts. Juvenile brownish above, with pale brown scaling on coverts, and dark grey primaries; upper mandible and tip of bill blackish.
Habitat. A tropical coastal species, often found at sea, but very rare inland. Nests on rock, sand, gravel or coral islands, often more than 100 m from sea. Forages mainly within 3 km of land, mainly over coral reefs; in Kenya regularly 5-10 km offshore.
Food and Feeding. Small fish (average 5 cm) and invertebrates. In Egypt, mainly silverside (*Atherinomorus lacunosus*) and clupeids (*Spratelloides*). Feeds by plunge-diving, but more often by contact-dipping. Often lands on water, or walks in shallow water. Associates with predatory fish and marine mammals; follows fishing boats.
Breeding. May-Jun in Sudan and Oman, Jul-Sept in Egypt, Somalia and Kenya. In mixed colonies with other terns, e.g. *Thalasseus bengalensis*, *T. bergii*, *S. dougallii*, *S. anaethetus*, *S. fuscata*; usually in scattered colonies of 10-200 pairs, but up to 900 pairs (Egypt). Forms discrete, synchronous subcolonies on barren or sparsely vegetated areas. Nearest-neighbour distance from as little as 46 cm, but average up to 4·6 m; 0·5-3 nests/m². Shallow scrape, often unlined. 2-3 eggs (1-3); incubation and fledging not documented, but chick dependent on parents for weeks after fledging; chick buffy above with black spots, whitish below with black chin, and buffy tinge to belly; fledglings may form crèche at water's edge. Productivity not recorded, but avian predators are serious threat in some colonies.
Movements. Present Red Sea Apr-Sept, Egypt Apr-Nov, E Africa throughout year (peak Mar-Jun). Persian Gulf mainly Sept-Apr. Common on Sind coast of Pakistan Mar-May, but does not breed. Egyptian birds may disperse N after breeding, making stopover near Hurghada, before migrating out of Red Sea; probably winter along E African and Indian coasts. Common spring migrant along coasts ofPakistan and Kenya, but corresponding autumn migration probably offshore.
Status and Conservation. Not globally threatened. Total population variously estimated at 20,000-70,000 birds. Colony of 21,000+ pairs discovered off Abu Dhabi in 1994; c. 10,400 pairs off Saudi Arabia in early 1990's; minimum 2000 pairs in Oman, but flock estimated at 70,000 birds roosting at Masirah I in 1979. In 1972, reported 300,000 pairs in 60 ha on Sheedvar I (Iran), but by 1976/77 only 25,000-50,000 pairs recorded, with decline attributed to massive egg-collecting by local islanders. Subject to egging in many areas, and suffers losses to avian predators; at Kiunga Is (Kenya), latter include Intermediate Egret (*Egretta intermedia*), Sacred Ibis (*Threskiornis aethiopicus*) and Yellow-billed Stork (*Mycteria ibis*).
Bibliography. Ali & Ripley (1982), Ash & Miskell (1983), Britton (1971, 1982b), Britton & Brown (1974), Brown & Britton (1980), Bundy (1988), Cramp (1985), Dowsett & Forbes-Watson (1993), Étchécopar & Hüe (1964), Evans (1994), Gallagher *et al.* (1984), Goodman *et al.* (1989), Hüe & Étchécopar (1970), Mackworth-Praed & Grant (1957), Moore & Balzarotti (1983), Olsen & Larssen (1995b), Paz (1987), Perennou *et al.* (1994), Rands *et al.* (1987), Ripley (1982), Roberts, T.J. (1991), Shirihai (1996), Short *et al.* (1990), Symens (1991), Symens & Evans (1993), Urban *et al.* (1986), Walker & Turley (1989).

28. **Black-bellied Tern**

Sterna acuticauda

French: Sterne à ventre noir **German**: Schwarzbauch-Seeschwalbe **Spanish**: Charrán Ventrinegro

Taxonomy. *Sterna acuticauda* J. E. Gray, 1832, Kanpur, India.
In past, commonly listed as *S. melanogaster*, but name *melanogaster* was preoccupied. Monotypic.
Distribution. Pakistan (R Indus), Nepal and most of India E to SW China (W Yunnan), and S through Myanmar, N Thailand, Laos, Cambodia and S Vietnam.



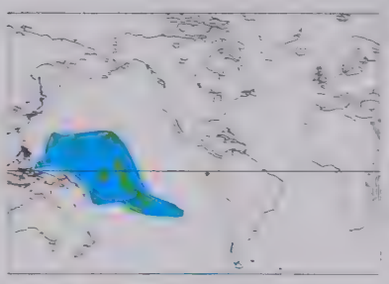
Descriptive notes. 32-35 cm. Typical tern from above, with black cap and grey back and wings, latter long and pointed; throat white, breast pale grey shading into deep black and brownish black belly and undertail-coverts; dark underparts contrast with white underwing, latter with darker band across secondaries; bill yellow-orange; legs reddish orange. Non-breeding adult has white forecrown streaked with black, black band behind eye, whitish underparts mottled black on belly, and black tip to bill. Juvenile has red at base of lower mandible and blackish feet; can be confused with "*portlandica*" plumage of *S. hirundo*, but darker.
Habitat. Inland lakes and rivers, preferring broad, barren, featureless flats, sand spits and sandy islands in rivers. Feeds along rivers and lakes, and over paddies, ditches and village ponds. Occurs up to 700 m in Nepal.
Food and Feeding. Insects and small fish. Plunge-dives for fish, and aerial-dips for insects over water and land. Despite non-colonial breeding, occasionally feeds in flocks.
Breeding. Feb-Apr. Early nests sometimes flooded. Often breeds with *S. aurantia*, skimmers and pratincoles, but not colonial; nests very widely spaced, often over 1 km and essentially solitary. Shallow, unlined scrape in bare sand, sometimes near a small object; usually more than 200 m from water's edge. Clutch 3 eggs, sometimes 2, rarely 4; incubation and fledging not studied, and reports of 15-16 days and 8 weeks, respectively, certainly erroneous; parents shade eggs and chicks, and also sprinkle water from belly feathers; adults mob intruding birds and predators. Productivity: one report of 0·7 young/nest.
Movements. Not migratory. Virtually unknown away from breeding sites.
Status and Conservation. VULNERABLE. Total population believed to number fewer than 10,000 individuals, and in continuing decline. Now very rare, possibly extinct, in Thailand; disappearing from Laos and Cambodia; no more than 25 pairs in Myanmar. Said to be common resident in Nepal, and fairly common in N & C India, but virtually unstudied. Destruction of breeding habitats is a major threat; eggs widely collected for food; and nests subject to flooding. Wide nest dispersion presumably an adaptation to heavy pressure from terrestrial predators, including man.
Bibliography. Ali & Ripley (1982), Collar *et al.* (1994), Deignan (1945), Etchécopar & Hüe (1978), Harvey (1990), Inskipp & Inskipp (1991), Lekagul & Round (1991), Lowe (1933), Lowther (1949), Meyer de Schauensee (1984), Mundkur (1988), Neelakantan (1953a), Perennou *et al.* (1994), Ripley (1982), Roberts, T.J. (1991), Rose & Scott (1994), Smythies (1986).

29. Aleutian Tern

Sterna aleutica

French: Sterne des Aléoutiennes **German**: Aleutenseeschwalbe **Spanish**: Charrán Aleutiano
Other common names: Kamchatka Tern

Taxonomy. *Sterna aleutica* Baird, 1869, Kodiak Island, Alaska.
Listed as *S. camtschatica* by many authors, particularly in Russia. Monotypic.
Distribution. Sakhalin through Sea of Okhotsk to Kamchatka and perhaps other sites in Bering Sea: Alaska, on Bering and Pacific coasts, from Chukchi Sea and Kotzebue Sound S to Aleutian Is, and E to delta of Copper R and Dry Bay; has bred in Japan (Hokkaido). Main wintering area unknown, although some birds in Philippines.



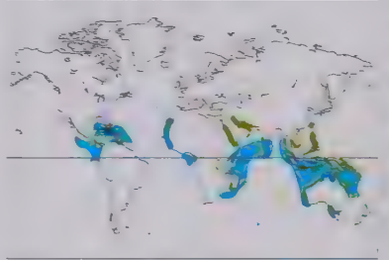
Descriptive notes. 32-34 cm; 83-140 g; wingspan 75-80 cm. White forehead, black cap and lores, mid-grey back and wings, white rump and tail, and darkish grey underparts; underwing whitish, with dark-tipped primaries and dark bar on secondaries; bill and legs black. Distinguished from *S. paradisaea*, even when forehead and soft parts not seen, by darker plumage, slower wingbeats, more floating flight, and by distinctive call, a squeaky 3-note whistle. Non-breeding adult similar to non-breeding *S. paradisaea*, but with dark secondaries. Juvenile has smoky brown crown and upperparts, latter with sandy feather edges, and often yellow-brown sides of breast.
Habitat. Arctic and subarctic coastal plains, mainly around Bering Sea. Partially vegetated sandy and shell beaches and grassy meadows, mossy flats, bogs and marshes on isolated rocky islands or along coasts, often near river mouths; occasionally in bogs 20 km inland. In Kamchatka and Sakhalin prefers grassy areas. Usually more coastal than either *S. paradisaea* or *S. hirundo*, with which often nests. In Kamchatka feeds mainly at river mouths, estuaries and along seashore, rarely over marshes. Pelagic when not breeding.
Food and Feeding. Mainly small fish. On Sakhalin primarily sticklebacks (*Pungitus pungitus*, *Gasterosteus aculeatus*). Feeds both at sea and over inland water bodies. Only contact- and surface-dipping observed, even in places where other species seen plunge-diving. Not reported to engage in kleptoparasitism. On Sakhalin, fed up to 40 km from colony.
Breeding. Laying mainly Jun. Usually small, monospecific colonies of 4-150 pairs, but up to 700 pairs on Sakhalin; occasionally solitary, or as single pairs in *S. paradisaea* colonies. Monospecific colonies often uniquely quiet; disturbed adults leave quickly and do not mob. Nearest-neighbour distance 2-16 m, but mean of 31 m reported in one colony; 4-24 m in Sakhalin, with average 17·7 m; nests more widely spaced in monospecific colonies. Nest-site sometimes among tall grasses and sedges, or in berry bushes. Scrape in sand, pebbles, among rocks, mosses, or on matted grass, even on bog hummocks; often assembles grassy nest, sometimes raised above wet substrates, but also lays directly on sand with no scrape. 2 eggs (1-4), average 1·3 (Kamchatka) to 1·84 (Sakhalin); incubation c. 22-27 days; chick has down feathers dark at base and pale grey or tan at tip, creating grizzled appearance similar to *S. dougallii*; hatching weight reported as low as 11·2 g; chick remains in nest 1-4 days, then hides in nearby vegetation; fledging 26-28 days; dependent young remain at colony for 2 weeks. Hatching success low: only 21% (Sakhalin) to 50% (Kamchatka); most eggs lost to predators; chick mortality also high.
Movements. Little information. Arrives in breeding areas mid-May and leaves by mid-Sept. Non-breeders presumably pelagic, dispersing into Bering Sea and N Pacific. No Nearctic records outside Alaska, and only accidental in Commander Is and Japan. Winter records from Philippines, and recorded as migrant Hong Kong, but main wintering areas still unknown. One extraordinary record of vagrancy: an adult in Britain in May 1979.
Status and Conservation. Not globally threatened. Virtually endemic to Bering Sea, with total population possibly below 15,000 pairs; relatively few known breeding areas. Occupies a sparsely studied area of the world. Alaskan census in mid-1970's found 850 pairs in 28 colonies, resulting in an estimated population of 5000-10,000 pairs. Copper Delta holds at least 1000 pairs. Kamchatka (where first found breeding in 1973) holds 500 pairs in at least 14 colonies; Sea of Okhotsk 1000 pairs; Sakhalin 2100 pairs. Predation by corvids and gulls on eggs, and by foxes and mustelids on chicks and adults, locally significant; predation by river otter (*Lutra canadensis*) on adults reported. Food apparently a limiting factor, as young chicks experienced slower growth and higher mortality than *S. paradisaea* in same colony.
Bibliography. Anon. (1993c, 1994f), Armstrong (1983), Baird & Moe (1978a), Bent (1921), Brazil (1991), Buckley & Buckley (1979), Cramp (1985), Davidova & Korotitskaya (1977), Dementiev & Gladkov (1951b), Duffy (1995), Gabrielson & Lincoln (1959), Haney, Andrew & Lee (1991), Harrison (1984a), Kaverkina (1979, 1982, 1986b, 1989, 1990), Kennerley *et al.* (1993), Kessel & Gibson (1978), Knystautas (1993), Kovalev *et al.* (1980), Lee (1992), Lensink (1984), Leonovitch (1976b), Litvinenko (1986), Litvinenko & Shibaev (1991), Lobkov (1976), Lobkov & Golovina (1978), Lobkov & Nechaev (1986), Nechaev (1977, 1981), Olsen & Larssen (1995b), Sowl (1979), Sowls *et al.* (1978), Stepanjan (1990b), Voronov & Eremin (1982)

30. Grey-backed Tern

Sterna lunata

French: Sterne à dos gris **German**: Brillenseeschwalbe **Spanish**: Charrán Lunado
Other common names: Spectacled Tern

Taxonomy. *Sterna lunata* Peale, 1848, Tuamotu Islands.
Formerly united with *S. fuscata* and *S. anaethetus* in separate genus *Haliplana* or *Onychoprion*. Monotypic.
Distribution. Northern Mariana Is E through Wake I and N Marshall Is to Hawaiian Is, and S through Phoenix and Line Is to Fiji, then E to Austral and Tuamotu Is; also Easter I (at least formerly); possibly also Samoa and Society Is. Wanders irregularly W to N Moluccas.
Descriptive notes. 38 cm; 115-177 g; wingspan 73-76 cm. Somewhat reminiscent of *S. fuscata*, but with grey upperparts and upperwings; white forehead patch smaller, but extends further back over eye; relatively short-winged, with very short inner wing. Non-breeding adult has forecrown faintly streaked white. Juvenile has less clear-cut head pattern, and buff scalloping on upperparts; sides of breast dusky.
Habitat. Oceanic islands of tropical Pacific, breeding on low sea cliffs, sandy beaches or bare ground on coral or rocky islands. Pelagic outside breeding season.
Food and Feeding. Mainly small fish, e.g. clupeids and flying-fish (Exocoetidae), and squid; one of the few terns occasionally to take lizards (at Enderbury I, Phoenix Is). Feeds mainly inshore, often with other terns. Takes tiny fish by plunge-diving. Often contact-dips or hover-dips over schools of tuna. Seizes lizards from vegetation by swooping down in flight.



Breeding. Long breeding period, Feb-Sept, with peak Mar-Jul; breeds c. 1-2 months earlier than [illegible]
colonies. Nest-site on rocky ledge, cliff, or on ground under vegetation, also on piers; usually higher on slopes than *S. fuscata*; also in shallow cavity and ledge or cliff, and hollow in rocks. 1 egg; incubation 24-35 (usually 29-30) days; fledging 7 weeks. Oldest ringed bird 16 years, but no doubt lives longer.
Movements. After breeding, abandons colony in Aug and presumably "winters" pelagically in Pacific. Non-breeders recorded from Palau Is and Yap I (Caroline Is), and also infrequently W to Halmahera (N Moluccas).
Status and Conservation. Not globally threatened. Line Is and Phoenix Is each hold 10,000's of pairs. Said to be common formerly on Easter I, but current status there uncertain. Rare in Micronesia. Wide disparity in estimates from Hawaii Is, from 18,000 to 51,000 pairs. Subject to heavy rat predation on Midway, Kure and other islands. Suffers high chick mortality from later-arriving *S. fuscata* which settle on its colony. On some islands, many nests lost to high tides.
Bibliography. 31. Bridled Tern

Sterna anaethetus

French: Sterne bridée **German**: Zügelseeschwalbe **Spanish**: Charrán Embridado
Other common names: Brown-winged Tern

Taxonomy. *Sterna Anaethetus* Scopoli, 1786, Panay, Philippines.
Formerly united with *S. fuscata* and *S. lunata* in separate genus *Haliplana* or *Onychoprion*. Geographical variation subtle, and subspecific divisions probably exaggerated; taxonomy in need of revision; validity of forms named as *novaehollandiae* (Queensland to S Australia) and *rogersi* (N Western Australia) requires further study. Six subspecies currently recognized.
Subspecies and Distribution
S. a. melanoptera Swainson, 1837 - W Africa.
S. a. fuligula Lichtenstein, 1844 - Red Sea and E Africa through Persian Gulf and Arabian Sea to W India.
S. a. antarctica Lesson, 1831 - Madagascar, Aldabra, Seychelles and Mascarenes through Maldives to Andaman Is.
S. a. anaethetus Scopoli, 1786 - extreme S Japan (S Ryukyu Is) and Taiwan; S through Philippines and Indonesia to Australia, including Lord Howe I and Norfolk I.
S. a. nelsoni Ridgway, 1919 - W coast of Mexico and Central America.
S. a. recognita (Mathews, 1912) - West Indies, Belize and islands off N Venezuela.

Descriptive notes. 35-38 cm; 95-150 g (Great Barrier Reef 125-135, average 131); wingspan 76-81 cm. Semi-pelagic tern with long, deeply forked tail and long, narrow wings; forehead patch white and triangular, extending short way behind eye; crown and nape black, occasionally with narrow paler hindneck collar; upperparts dark grey-brown, paler on rump and tail, with white outer tail feathers; upperwing dark grey-brown, with conspicuous pale leading edge; whitish below, with grey breast; bill and legs black. Shorter-winged than than *S. fuscata*, and 10% smaller, with paler upperparts contrasting with black crown, and narrow white eyebrow extending further behind eye; unlike *S. fuscata*, bill tomia not serrated, and webbing of toes more deeply incised which may facilitate perching on vegetation. Non-breeding adult somewhat paler, crown and nape with whitish and brownish streaks, reducing conspicuousness of white eyebrow. Juvenile has white forehead and supercilium and blackish brown hindneck, with crown and nape streaked grey and white; dark brown above, with broad whitish scaling, dark brown flight-feathers. Immature paler brown, with white-edged feathers, crown brown and speckled with grey, black head pattern more obscure. Races differ mainly in darkness of plumage, amount of white in outer tail, and size; *melanoptera* somewhat paler above, with greyish collar between nape and upperparts.
Habitat. Pantropical, occurring on tropical and subtropical coasts. Breeds on coral beaches and rocky and sandy slopes. Forages inshore and offshore, up to 50 km from land; mostly within 15 km, hence less pelagic than *S. fuscata*. Often perches on floating objects and on trees at night; roosts on sandbanks or rocky beaches, also in trees (Seychelles); reports of roosting on sea not corroborated.
Food and Feeding. Mainly surface-schooling fish (93%) and squid; 97% of fish less than 6 cm; also crustaceans; occasionally aquatic insects. Prefers various flying-fish at Los Roques (Venezuela) and in Ryukyu Is, filefish at Puerto Rico, Mullidae in Seychelles (90%), anchovy (*Engraulis australis*) and monacanthids on Great Barrier Reef, and marine insects (*Halobates*) in Sri Lanka. Flocks feed over shoals of small fish; only occasionally with *Anous* over schools of predatory fish. Feeds by plunge-diving without submerging, or contact-dipping from 1 m; also by surface-dipping or aerial-dipping, often over drifting seaweed. Sometimes forages up to 28 km from colony.
Breeding. May-Jun in S Caribbean and W Africa, Jun-Aug in E Africa, Jul-Aug in Madagascar, Oct-Dec in Australia. Most populations breed annually; 7-6-month cycle in Seychelles, with nesting in any month. Usually associates with *S. fuscata*, sometimes with *Thalasseus bergii*. Colonies of 3-20 pairs, up to 400 pairs, but 500-2000 pairs in W Australia; often not synchronous. Nests often disturbed in vegetation, rock or rubble around rim of island, rather than clustered; spacing dictated by nest-site availability, usually 1-5 m, minimum 30 cm; 70% of birds retain nest-site from year to year, even with different mates. Nest contents normally concealed under rock or vegetation, reducing predation; reported to give broken-wing display to humans near nest. 1 egg, 2-egg clutches believed to be product of 2 females; incubation 28-30 days; chick finely mottled (not spotted), resembles that of *S. dougallii*; hatching weight 16-20 g, young do not form crèches; fledging 50-65 days; dependent young remain around colony a further 30-35 days. Productivity often high: 90% of eggs hatch and 77% of chicks fledge. May visit colony late in breeding season at 3 years, but first breeding usually at 4 years. Recorded longevity of 17 years 11 months; doubtless lives longer.
Movements. Virtually unknown for most areas. Widespread at sea. Birds from West Indies and Atlantic probably move E to upwellings off W Africa. Some Seychelles birds appear on E coast of Africa.

Australian breeders leave colonies in Mar, but movements unknown. Heavy southward autumn movement past Colombo, Sri Lanka, with estimate of 125,000 migrating S in Aug 1974, and possibly twice that number in 1978. Rare visitor to coasts of USA and Europe, usually after hurricanes.

Status and Conservation. Not globally threatened. Population figures unknown, but world total probably exceeds 200,000 pairs. Centre of abundance probably in Persian Gulf, where over 40,000 pairs counted off Abu Dhabi in 1994, also c. 34,400 pairs off Saudi Arabia in early 1990's, and 25,000-27,000 pairs in Iran; also minimum of 31,000 pairs off Oman. Usually nests with or close to *S. fuscata*, but almost always much less numerous. Predation by Yellow-crowned Night-herons (*Nycticorax violaceus*) observed at Los Roques, Venezuela. Jackals take young and adults in W Africa. Human predation low, owing to hidden nests; but human intrusion to colonies causes some damage.

Bibliography. 32. Sooty Tern

Sterna fuscata

French: Sterne fuligineuse **German**: Rußseeschwalbe **Spanish**: Charrán Sombrío
Other common names: Wideawake (Tern)

Taxonomy. *Sterna fuscata* Linnaeus, 1766, Santo Domingo.

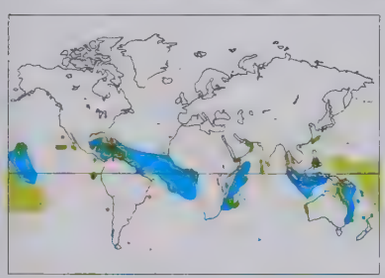
Formerly united with *S. anaethetus* and *S. lunata* in separate genus *Haliplana* or *Onychoprion*. Geographical variation subtle: separation of races *crissalis*, *infuscata* and *serrata* probably not warranted; validity of proposed form *somaliensis*, possibly endemic to Mait I (Gulf of Aden), requires study. Eight subspecies currently recognized.

Subspecies and Distribution.

S. f. fuscata Linnaeus, 1766 - Gulf of Mexico, including West Indies and E Mexico, with sporadic isolated nesting attempts in the Carolinas and Florida, more regularly in Louisiana and Texas; also islands in Gulf of Guinea and in S Atlantic.

S. f. nubilosa Sparrman, 1788 - S Red Sea, Gulf of Aden and Indian Ocean E to Ryukyu Is and Philippines.

S. f. infuscata Lichtenstein, 1823 - C Indonesia (range uncertain).



S. f. serrata Wagler, 1830 - New Guinea, Australia and New Caledonia.

S. f. kermadeci (Mathews, 1916) - Kermadec Is.

S. f. oahuensis Bloxham, 1826 - Bonin Is to Hawaii and S through Pacific.

S. f. crissalis (Lawrence, 1872) - islands off W Mexico and Central America S to Galapagos.

S. f. luctuosa Philippi & Landbeck, 1866 - Juan Fernández Is (Chile).

Descriptive notes. 36-45 cm; 147-240 g, average 173 g in Australia and on Kiritimati I (Christmas I, Pacific), 175 g on Ascension I, 189 g in Dry Tortugas; wingspan 82-94 cm. Distinctive black and white tern, with long wings and long tail; very noisy, with yelping "wide-a-wake" call at breeding colony; black above, sometimes with brownish cast, white below (in flight, often reflecting pale blue from water), and with white forehead with black line from bill to eye; deeply forked tail black, except for white outer rectrices; underwing blackish grey, with contrasting white coverts; bill and legs black, bill with tomia serrated; iris dark brown. Separated from *S. anaethetus* by darker and more uniform upperparts, lack of white eyebrow, and underwing pattern. Non-breeding adult has variable white feather fringes above. Juvenile blackish brown above, finely vermiculated and spotted with white, and grey-brown below, becoming paler from lower belly downwards. Races differ only slightly; *nubilosa* has pale grey tinge to belly and underwing-coverts; *oahuensis* and *kermadeci* are larger-billed.

Habitat. Pantropical, in tropical and subtropical waters; largely absent from cold-current areas; mainly productive waters rich in plankton and conducive to fish and squid abundance. Breeds on oceanic and barrier islands of sand, coral or rock, including artificial islands; usually flat, open and with sparse vegetation, but often heavily vegetated, e.g. Culebra (Puerto Rico); eschews islands with terrestrial predators. Highly pelagic outside breeding season; vagrants occur inland after hurricanes.

Food and Feeding. Mainly fish and squid, also crustaceans; occasionally insects and offal. At Kiritimati, squid comprise more than half the diet by volume, and both fish and squid regurgitated at most feeds. In Hawaii, fish and squid about equal in diet; fish mainly 6-8 cm, but up to 18 cm, with 21 families, of which flying-fish (Exocoetidae) and Scombridae predominant; most common prey was yellowfin (*Neothunnus macropterus*). Feeds mainly by aerial-dipping or contact-dipping; occasionally by plunge-diving; flying-fish caught in air. Unable to swim and very rarely seen to rest on water, as becomes waterlogged. Feeds at night on bathypelagic fish which come to surface only in darkness. At Ascension I feeds far at sea, possibly over 500 km from colony, but in Tortugas mainly within 80 km.

Breeding. Breeds all year round in some places, but seasonal in others; cycle on Ascension 9·6 months. Dec in Laccadives, Feb at Kermadecs and in Brazil; at Oahu (Hawaiian Is) lays Apr-May on Manana I, but 15 km away on Moku Manu some nest in Nov; Apr-May in Dry Tortugas, May in Greater Antilles, Jun-Jul in Seychelles, Nov in Tanzania. In many areas all first layings harvested, artificially retarding breeding by c. 1 month. Normally large to huge colonies; occasionally single pairs colonize new areas (e.g. one pair in *S. dougallii* colony on Madeira in 1982, first W Palearctic breeding record). Courtship and copulation often synchronous. Most nest-sites flat, open sand, shell or coral with sparse vegetation, but many are heavily vegetated (e.g. Culebra). Prefers vegetative cover where available, usually selecting the tallest, yet in Ryukyu Is tall grass succession excluded terns from former nesting area. Lays on bare areas, sometimes making slight depression. Nests dense, c. 50 cm apart; 3·38 nests/m² at Bird I (Seychelles); clusters of pairs may be constant from year to year. 1 egg, rarely 2; incubation 26-33 days, mainly 28-30; chick buffy brown, sparsely and obscurely splotched dark brown; grows more slowly than typical *Sterna*, fledging c. 2 months. In unvegetated colonies some chicks succumb to heat exposure. Productivity: 70% of eggs produce chicks at Tortugas except in hurricane years, but only 2-20% on Ascension I; up to 75% of chicks fledged at Manana. Occasionally subject to mass starvation and breeding failure, e.g. Ascension in Jan 1959. A few attempt nesting as early as 4 years, some not until 10, but first breeding usually at 6-8 years. Recorded longevity of 32 years.

Movements. Rarely seen on water and believed to sleep on the wing. Once chicks fledge (or die), all birds leave colonies. Adults return after 2-3 months at sea, and settle only at night for 2-3 months prior to initiating new breeding cycle. Adults from West Indies disperse into Gulf of Mexico and Caribbean where some winter; juveniles cross Atlantic and move S down African coast. Little information on Indian Ocean population, which probably disperses widely over Indian Ocean. Pacific adults disperse away from colony Jun-Oct and begin to return to area in late Nov, occupying colony in Feb, but not laying until Apr (Johnston Atoll).

Status and Conservation. Not globally threatened. One of most abundant seabirds, with several colonies of 1,000,000+ pairs. Total world population probably exceeds 25,000,000 pairs. Huge numbers in S Pacific, with over 10,000,000 in Line Is and over 1,000,000 each in Phoenix Is and Marquesas. About 1,500,000 breed in Hawaii, and a further 5,000,000 birds may breed from Indian Ocean to W Australia. Many marginal populations, however, are vulnerable. Conversely, new breeding attempts, often by single pairs, indicate range expansion, though these are often unproductive and impermanent. Most remote oceanic islands are free from terrestrial predators, but some colonies subject to rat and cat predation; at Ascension I, population has declined from 500,000 pairs (1954) to under 200,000 pairs (1994), largely due to cat predation. Many avian predators take eggs and chicks, which can significantly reduce productivity in some colonies. Hurricanes may completely eliminate productivity. Eggs sometimes harvested, such activities being partly managed in Seychelles and Jamaica. Tick infestation and arthropod-borne viruses have caused abandonment and abnormal chick development in Seychelles. Species also vulnerable to oil pollution from tankers and spills. Total hatching failure attributed to repeated low-flying by jet planes, although this has not been proven.

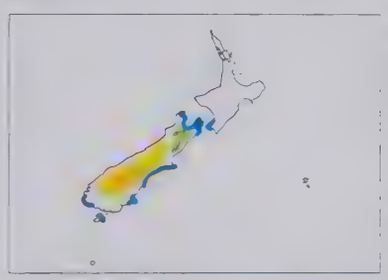
33. Black-fronted Tern



Sterna albostriata

French: Guifette des galets **German**: Graubauch-Seeschwalbe **Spanish**: Charrán Fumarel
Other common names: Tara (Maori)

Taxonomy. *Hydrochelidon albostriata* G. R. Gray, 1845, New Zealand.

Sometimes placed in *Chlidonias* even as race of *C. hybridus*, but is a typical *Sterna*. Species name sometimes misspelt *albistriata*. Monotypic.

Distribution. New Zealand, breeding in interior South I. Post-breeding visitor to North I, where formerly bred.

Descriptive notes. 30 cm; 88-96 g. Forehead to nape black, back and wings grey, with darker grey primaries, and underparts pale grey; uppertail- and undertail-coverts and rump white; tail pale grey with darker tips; outer primary has dark leading edge and white shaft; eye black; bill and feet bright yellow-orange. In breeding plumage Jun to late Nov, then undergoes complete moult from mid-Dec to May. Non-breeding adult has grey head with black patch around nape from eye to eye, and black-flecked crown. Juvenile has greyish brown crown and nape, mottled with black, and black ear-coverts and lores; mantle, back and wing-coverts brown, margined with buff; breast and belly grey, throat and undertail-coverts white; bill dark brown with orange base, feet orange. Immature similar to non-breeding adult, with grey body, black-mottled grey crown, and black patch on ear-coverts and nape; wings and tail brownish, with darker tips; bill dark brown, often with reddish orange base; legs and feet orange.

Habitat. Breeds mainly on gravel and sandy bars in fast-flowing braided rivers; also on lake beaches. Forages over lakes and farm fields. In winter, coastal harbours and estuaries, roosting on tidal flats and islands; seldom ventures more than 10 km offshore.

Food and Feeding. Small fish (up to 10 cm long), insects, beetles, grubs, earthworms and lizards; in winter, mainly crustaceans and fish. Feeds commonly by aerial-dipping to surface of rivers or lakes, but may also plunge-dive for fish; also by aerial hawking for swarming insects. Follows ploughs.

Breeding. Mid-Oct to late Nov, occasionally to Jan. Colonies from under 10 pairs up to 75; nearest-neighbour distance usually 5-20 m. Nest a vague depression in gravel at base of rock or bush, very difficult to find. 2 eggs; incubation 21-23 days; chick grey-brown to olive with dark speckles, dark patch on cheeks and lores, dark throat, white breast and belly, black-tipped dull chrome bill, orange feet; leaves nest within 4 days; adults very aggressive, attack intruders. Productivity usually low.

Movements. After breeding, birds move to coast of South I and to S North I and Stewart I. Vagrant to Snares and Chatham Is.

Status and Conservation. VULNERABLE. Total population estimated at 1000-5000 pairs in 1982, alternatively 10,000 pairs, but all figures no more than speculative. Although there are many colonies, most contain only a few to c. 25 pairs. Breeding habitat, rocky islets in rivers, dry river beds and lake shores, is threatened by encroachment of exotic plants, particularly lupins (*Lupinus*), and by tree-planting; also by proposed development of hydro-electric plants on rivers, and by introduced predators. Many nests or broods are lost to predation by cats and mustelids, trampling by sheep, and flooding.

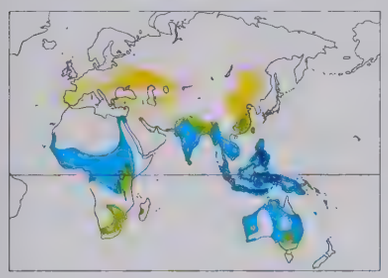
PLATE 57

inches 5
cm 13



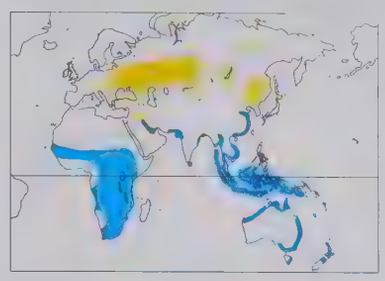
Genus *CHLIDONIAS* Rafinesque, 1822

34. **Whiskered Tern**

Chlidonias hybridus

French: Guifette moustac **German**: Weißbart-Seeschwalbe **Spanish**: Fumarel Cariblanco

Taxonomy. *Sterna hybrida* Pallas, 1811, southern Volga, Russia.
Genus sometimes merged into *Sterna*. *Sterna albostriata* sometimes considered a race of *C. hybridus*, but morphology and ecology more typical of *Sterna*. Race *swinhoei* may be inseparable from *javanicus*; proposed race *leggei* included in latter. All Eurasian populations often lumped in nominate *hybridus*. Six subspecies normally recognized.
Subspecies and Distribution.
C. h. hybridus (Pallas, 1811) - SW & C Europe through W Russia, Middle East and Transcaspia to SC & E Kazakhstan; winters mainly in Africa and also SW Asia.
C. h. swinhoei (Mathews, 1912) - Transbaikalia, E China and Taiwan.
C. h. indicus (Stephens, 1826) - E Iran and Pakistan to N India.
C. h. javanicus (Horsfield, 1821) - NE India and probably Sri Lanka; winters Malaysia to Indonesia.
C. h. sclateri (Mathews & Iredale, 1912) - Kenya to South Africa and Madagascar.
C. h. fluviatilis (Gould, 1843) - Australia; migrates to New Guinea and Moluccas.



Descriptive notes. 23-29 cm; 60-101 g (average 84 g); wingspan 64-70 cm. Slender, medium-small tern, with wings more rounded than in typical *Sterna*; shortish tail with only slight fork; forehead to nape black, with contrasting white cheeks; upperparts, including rump and tail, mid-grey; underparts grey, darker on belly, with contrasting pale grey underwing and white undertail-coverts; iris dark brown; bill dark reddish, legs red. Superficially resembles *Sterna paradisaea* and *S. repressa*, but darker below, with much shorter tail. Non-breeding adult very pale above and below, with dark-flecked pale crown, black patch behind eye merging into dark band across nape, and black bill; crown pattern less contrasting than in *C. niger*, but more complete than in *C. leucopterus*. Female significantly smaller than male in all dimensions. Juvenile has head pattern similar to non-breeding adult, but with face washed buff and hindneck tipped dark grey; mantle, scapulars and tertials contrastingly darker, with buff tips. Races differ somewhat in coloration of breeding plumage, but only slightly in size; *delalandii* darkest, with white cheek stripe narrower.
Habitat. Breeds on vegetated inland lakes, marshes and rivers, mainly in lowlands, but up to 2000 m in Armenia; in Italy prefers artificial fish ponds and drainage ponds covered with water-lilies; in Africa opportunistically seeks pans after heavy rains. In Australia mainly coastal, breeding in arid interior in very wet years. Feeds over lakes, marshes, and rice fields, but also over sprouted farm fields, and coastal lagoons, tidal mudflats and estuaries.
Food and Feeding. Terrestrial and aquatic insects, e.g. water beetles (Dytiscidae), Odonata and their larvae, grasshoppers, flying ants, spiders; also tadpoles and frogs, small crabs, small fish. In N Australia, 55 stomachs revealed c. 32% Coleoptera, 18% Odonata, 9% Hemiptera, and 9% spiders; fish made up 13% of items but 45% of weight, and frogs 2% of items and 6% of weight; males took more fish and fewer insects, and had more diverse diet. Flies back and forth or flutters 2-6 m above water, then swoops (aerial-dipping) or drops (hover-dipping) to pick up small surface items; infrequently engages in plunge-diving. Often hawks insects over fields and lake margins; sometimes feeds behind plough in Spain. Generally forages within 1 km of colony, occasionally up to 9 km.
Breeding. May-Jun in Europe, Nov-Dec in Australia, Dec in Tanzania. Forms synchronous subcolonies, usually in monospecific colonies of 10-100 pairs. Broad but flimsy nest of stems or decaying rushes, placed on floating or emergent vegetation over water, usually 60-80 cm deep; in very shallow water, nest may rest on bottom; alternatively nest of dry grass on water-lily leaves; may usurp grebe nest. Nests 1-5 m apart. 2-3 eggs; incubation 18-20 days; chick black-spotted buff, with black forehead, creamy breast, black bill and pink legs; can leave nest within 1 day and swim to vegetation; fledging 23 days; fed for few weeks after. Hatching success 66% in Australia. Many breed first at 2 years.
Movements. From W Europe migrates to W Africa; E European birds winter mostly in E Africa, with a few in S Middle East; those from Caspian and Turkestan zone winter from Iran to Pakistan and Sri Lanka, and possibly also E Africa. Migration of race *swinhoei* poorly known, but small numbers winter in Thailand; *indicus* is irregular migrant in Nepal, usually in small numbers. Australian birds mainly nomadic, but those from S Australia migrate N.
Status and Conservation. Not globally threatened. In much of W & C Europe breeding is occasional and irregular, and species may have declined; however, apparently abundant in Andalucia (S Spain), where possibly 100,000 pairs breed; perhaps an additional 25,000 pairs elsewhere in Europe. Probably several 10,000's of pairs in former USSR. Formerly bred in N Africa, from Morocco to Tunisia. In sub-Saharan Africa, breeds in small, scattered, often non-permanent colonies. In India, large quantities of eggs are collected for sale and for local consumption, causing population decline in certain areas of Kashmir. In Ukraine, fishermen collect eggs. Many nests lost to adverse weather, e.g. high winds and waves.

35. **White-winged Tern**

Chlidonias leucopterus

French: Guifette leucoptère **German**: Weißflügel-Seeschwalbe **Spanish**: Fumarel Aliblanco
Other common names: White-winged Black Tern

Taxonomy. *Sterna leucoptera* Temminck, 1815, Mediterranean coasts.
Genus sometimes merged into *Sterna*. More similar to *C. niger* than to *C. hybridus*, but closely related to both; has apparently hybridized with *C. niger*. Monotypic.
Distribution. NW Italy and C & E Europe E through Siberia, Transbaikalia and N Mongolia to Amurland; has bred in New Zealand. Winters in Africa, and from S Asia to Australia and New Zealand.

Descriptive notes. 23-27 cm; 42-79 g (average 66 g in Ukraine, 54 g in winter in Transvaal); wingspan 58-67 cm. Very distinctive, appearing markedly black and white: head, body and scapulars black, with contrasting white rump, tail and undertail-coverts; upperwing grey, with white lesser and median coverts; underwing pale grey, with all coverts contrastingly black; bill reddish black; legs bright to dull red. Non-breeding adult pale grey above, white below, and head white, with dusky crown and auricular patch; very like non-breeding *C. hybridus*, but dark of crown and ear-coverts usually separated by white supercilium, usually shows darker grey band across lesser coverts, and often diagnostic black bar on underwing. Moults back into breeding plumage in mid-Mar. Juvenile has blackish brown saddle and silver-grey wings, contrasting with white rump and collar.
Habitat. Breeds mainly inland, on vegetated freshwater lakes and swamps, and rice fields (Italy), from boreal forest to Mediterranean; up to 2000 m in Armenia. On passage and in winter occurs in variety of habitats, from inland lakes to rocky coasts, rivers, impoundments, lagoons and mangrove swamps. Often roosts on emergent branches of drowned trees or on pilings.
Food and Feeding. Mainly aquatic insects (especially Diptera, Odonata, Coleoptera), also terrestrial insects; occasionally small fish or tadpoles. Rarely fish may predominate, e.g. sardines (*Limnothrissa miodon*) in South Africa. In dry season in Africa, feeds on fish trapped in residual pools. Opportunistic; will congregate at outbreaks of caterpillars, e.g. of army moth (*Laphygma exempta*) in Uganda. Forages in variety of wetland habitats, including wet fields, and also over dry farmland and steppe; in New Zealand feeds along rocky riverbeds. Species is accomplished aerial feeder; uses contact-dipping, also hover-dipping, and hawks flying insects; does not plunge-dive.
Breeding. Apr-Aug, mainly Jun. May skip breeding in drought years. Breeds in small colonies of 3-100 pairs, mostly 20-40, occasionally over 100 pairs; usually monospecific, sometimes with other terns or with Little Gulls (*Larus minutus*) or Black-necked Grebes (*Podiceps nigricollis*); low colony site fidelity. Nest of water weed with shallow cup, built on mat of floating vegetation in water 30-120 cm deep, occasionally on dry shore or resting on bottom; nests widely spaced (10-30 m), but occasionally as close as 2·5 m. 2-3 eggs (average 2·8); incubation 18-22 days; chick buffy above, streaked with black, paler below with few dark spots, and pale patch surrounding eye; fledging 20-25 days. First breeding at 2 years.
Movements. Migratory. European and W Asian populations leave breeding grounds from late Jul to late Aug, wintering mostly in Africa; large flocks on E side of Sea of Azov in late Aug, and passing through E Mediterranean in Aug-Sept; negligible movement off W coasts, but species numerous in Senegal in Sept. A few occasionally winter on Black Sea. Common migrant through E Africa, mainly inland, occasionally on coast. In spring, large flocks pass through E Mediterranean, and massive numbers recorded at N Red Sea; at N Gulf of Aqaba, c. 20,000 in one afternoon in 1984, and total of 81,000 in 5-day period in 1990. C & E Asian breeders winter from Burma and SE China, S through Indonesia and Indochina to Australia and New Zealand; wintering birds in Persian Gulf, Pakistan, Sri Lanka and elsewhere in N Indian Ocean may come from these populations.
Status and Conservation. Not globally threatened. True status not known over most of its range. Many populations probably vulnerable. Very scarce in C Europe, where breeds rarely or sporadically, but fairly common in parts of E Europe and C & E Asia; very common in steppes of Kazakhstan; perhaps several 100,000's of pairs in former USSR. Formerly bred in Algeria, and has bred once in New Zealand.
Bibliography. 36. **Black Tern**

Chlidonias niger

French: Guifette noire **German**: Trauerseeschwalbe **Spanish**: Fumarel Común

Taxonomy. *Sterna nigra* Linnaeus, 1758, near Uppsala, Sweden.
Genus sometimes merged into *Sterna*. Two subspecies recognized.
Subspecies and Distribution.
C. n. niger (Linnaeus, 1758) - S Scandinavia S to S Spain, and E through E Europe and W Asia to L Balkhash and Altai; winters in Africa.
C. n. surinamensis (Gmelin, 1789) - Great Slave L, S Mackenzie and C Manitoba S to California, and E to Great Lakes, NW Pennsylvania and NW New York, with disjunct populations in Kansas, Indiana and N Vermont; winters in Central America and N South America.

On following pages: 37. Large-billed Tern (*Phaetusa simplex*); 38. Brown Noddy (*Anous stolidus*); 39. Black Noddy (*Anous minutus*); 40. Lesser Noddy (*Anous tenuirostris*); 41. Blue Noddy (*Procelsterna cerulea*); 42. Grey Noddy (*Procelsterna albivitta*); 43. White Tern (*Gygis alba*); 44. Inca Tern (*Larosterna inca*).

Descriptive notes. 23-28 cm; 60-74 g (average 64 g); wingspan 57-65 cm. Distinctive small dark tern; head, neck and breast black, becoming more dark slaty grey on back and belly, with grey upperwing and tail; vent and undertail-coverts white; underwing grey; bill black; legs blackish-red. Shows slight sexual plumage dimorphism, probably the only tern to do so: breeding female greyer, with dull black on head restricted to crown. Non-breeding adult pale grey above, white below with characteristic dark patch on side of breast; head white, with contrasting dusky blackish central crown that meets black patch behind eye, and with dark spot in front of eye. Juvenile as non-breeding adult, but with pale brown wash on forehead, and back and scapulars grey-brown with pale buffish fringes. Race *surinamensis* smaller and darker; non-breeding adult and juvenile differ from nominate in having pale streaks on the dark crown, and more extensive dark patch on side of breast.

Habitat. Breeds on well vegetated inland pools, lakes, peat bogs and marshes, rice fields (Italy), and brackish marshes, with water usually 1-2 m deep; prefers sparse, open vegetation of bulrush and cat-tail (*Typha*) and other emergents, or floating water-lilies. Generally avoids marshes under 4 ha in extent. Forages over wetlands, but also in drier areas. On passage occurs on coasts and estuaries, but also at virtually any wetland, including even small ponds and ditches. Often roosts on emergent branches of drowned trees or on pilings. In winter found on estuaries, coasts and coastal lagoons.

Food and Feeding. Aquatic insects (particularly Coleoptera), small fish, snails, tadpoles and frogs. In breeding season mainly insects, including chironomids, Odonata, Ephemeridae; in analysis of 270 stomachs, fish formed 19% of diet. Insects comprise over 85-90% of nestling food. Usually feeds by aerial hawking and contact-dipping, occasionally hover-dipping, and more rarely plunge-diving. May feed 2-5 km from colony. Migrants feed in estuarine and coastal habitats, and flocks coalesce over schools of predatory fish; in Mediterranean, reported feeding in flocks over dolphins and tuna. Usually does not feed at night.

Breeding. May-Jun in Europe and North America. Some assortative mating, larger males mating with larger females. Most colonies contain fewer than 20 pairs, rarely more than 100; predation highest in small colonies. Usually nests over water, at least 50 cm deep; also on muskrat (*Ondatra zibethicus*) houses, boards, or old grebe or coot nests; prefers smaller, lower and wetter sites than *Sterna forsteri* in North America. Assembles mass of floating vegetation, or selects clump of dead reeds or cat-tail rootstalks. Nests usually more than 3 m apart in USA; sometimes 1·5-2 m in Ukraine, but often 20-100 m. Clutch 2-3 eggs, average 2·2-2·6; incubation 20-23 days (reports of under 20 days probably erroneous); adults leave nest early when intruders approach, and do not mob; chick similar to that of *C. leucopterus*, but paler, with dark chin and throat; fed within 2 hours after hatching; fledging 25 days. Nest success 20-40%; hatching success 52-70%; fledging success 1·3-2·1 chicks/pair. Recorded longevity of 17 years.

Movements. North American birds migrate to both Pacific and Atlantic coasts, wintering from Mexico (rarely) and Panama S to Peru, and from the Gulf Coast to N South America; accidental in Chile and Argentina. Many non-breeding birds, failed breeders or early migrants reach the coast by mid-summer; fairly common (formerly abundant) migrant off both coasts of Costa Rica; 1st-years summer along Pacific coast. Arrives back on breeding grounds in Apr. Palearctic birds often disperse N after breeding, with sometimes very large concentrations e.g. in S North Sea; migrates in huge numbers through Mediterranean, and also across N Africa (even over deserts), to main wintering grounds on tropical W African coasts from Mauritania to Namibia, some reaching South Africa; some winter in Nile Valley. Adults begin southbound migration by Aug, juveniles about a month later. Occasional birds linger over winter on Black and Caspian Seas.

Status and Conservation. Not globally threatened. World population may be of order of 500,000 pairs, including several 100,000's in former USSR (43,000 in Belarus), 25,000 in W Europe, and possibly 100,000 in North America. Many local populations vulnerable and declining; decreasing severely in many areas owing to wetland reclamation, with some local increases due to protection. Serious decline in E USA, and now rare or absent in coastal areas where flocks of 100's or 1000's seen in migration prior to 1970; along upper Niagara R (New York) typical numbers were 2000-5000 in 1965, but only 30-60 in 1987. Many nests are lost through storms and wave action, muskrat activity or predators; also when falling water level allows access to animals, including pigs. Main long-term cause of decline is loss of freshwater marsh habitat for agriculture, or through overgrowth of cat-tail, and human disturbance. Herbicide treatment of cat-tail has provided both open water and mats of dead vegetation, attracting nesting terns; but some suitable marshes are now unoccupied as well. Pesticides believed to have played some role in species' decline, either through direct poisoning or by eliminating aquatic prey and vegetation. Introduction of peacock bass (*Cichla ocellaris*) to Gatun L, Panama, eliminated the silverside (*Melaniris chagresi*) used for food by this tern, forcing it to winter elsewhere.

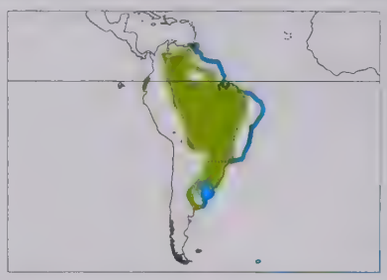
Genus *PHAETUSA* Wagler, 1832



37. Large-billed Tern

Phaetusa simplex

French: Sterne à gros bec **German**: Großschnabel-Seeschwalbe **Spanish**: Charrán Picudo

Taxonomy. *Sterna simplex* Gmelin, 1789, Cayenne.
Morphometric analysis does not provide clear evidence of relationship to other terns or gulls, but apparently most similar to *Thalasseus*. Two subspecies recognized.

Subspecies and Distribution.
P. s. simplex (Gmelin, 1789) - E Colombia E to Trinidad, and S through Amazonia; W Ecuador.
P. s. chloropoda (Vieillot, 1819) - basins of R Paraguay and R Paraná SW to NC Argentina (Santiago del Estero, very rarely Cordoba); non-breeding visitor to Uruguay.

Descriptive notes. 38 cm; 208-247 g. Unmistakable large, relatively short-tailed tern, with very heavy yellow bill, and striking wing pattern; crown to ear-coverts black; upperparts medium grey (darker than in most terns), but secondaries and greater wing-coverts white; lores and underparts white, sides of flanks tinged grey; iris blackish brown; legs and feet yellow. Conspicuous pattern in flight: black primaries, grey back, and triangular white patch on secondaries and coverts, reminiscent of Sabine's Gull (*Xema sabini*). Non-breeding adult has crown and forehead paler. Juvenile has less black on crown; back and wings mottled with brown; bill duller. Race *chloropoda* has slightly paler upperparts and brighter bill.

Habitat. Occupies broad (and occasionally narrow) inland rivers and lakes, breeding on beaches and sandbars; has bred once on coast (Rio Grande do Sul). Non-breeders also frequent coastal mangroves, beaches and estuaries.

Food and Feeding. Fish 4-12 cm long; also insects. Feeds mainly by plunge-diving from 6-11 m; also by contact-dipping (swooping about 2 m over water), hover-dipping, and occasionally skimming. Performs aerial hawking over mudflats, and follows plough (Surinam) to capture insects. Occasionally pirates food from conspecifics.

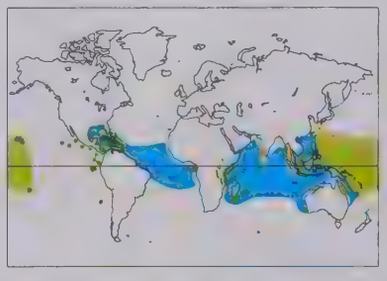
Breeding. May-Jun and Oct-Dec in N of range, Aug-Sept in Argentina. Nests singly or in groups of up to 100 pairs, mainly on sandbars with Black Skimmers (*Rynchops niger*), *Sterna superciliaris* and Sand-coloured Nighthawk (*Chordeiles rupestris*). Changes nest-sites from year to year. Usually no nest material. Up to 3 eggs (average 2·3). Few other published data. Productivity 1·66 young/nest. In Peru 68% of nests successful.

Movements. Winters on rivers and on coast. Common throughout year on Guyanan coast, with lower numbers May-Aug when breeding. Accidental in West Indies, Bermuda, Panama, and North America (Illinois, Ohio, New Jersey).

Status and Conservation. Not globally threatened. Very widespread E of Andes, and common along the length of R Orinoco, but population figures not known. Breeding beaches are frequently inundated, or subject to disturbance from humans or ungulates. Egg-collecting occurs, but unpredictability of colony locations and of breeding phenology mean that species is not currently threatened. Most nest failures are apparently due to flooding; adults and young sometimes eaten by boas (*Constrictor constrictor*).

Bibliography. Belton (1984), Blake (1977), Canevari *et al.* (1991), Chubb (1916), Contreras *et al.* (1990), Davis (1935), Escalante (1962), Fjeldså & Krabbe (1990), Groom (1992), Hartert & Venturi (1909), Hayes (1995), Haverschmidt (1968), Haverschmidt & Mees (1995), Hellmayr & Conover (1948), Hilty & Brown (1986), Kane *et al.* (1989), Krannitz (1989), Meyer de Schauensee & Phelps (1978), Murphy (1936), Olmos *et al.* (1995), de la Peña (1992), Preston (1962), Remsen (1990), Ridgely & Gwynne (1989), Sick (1985c, 1993), Snyder (1966), Teague (1955), Tostain *et al.* (1992), Vooren & Chiaradia (1990), Willard (1985).

Genus *ANOUS* Stephens, 1826



38. Brown Noddy

Anous stolidus

French: Noddi brun **German**: Noddi **Spanish**: Tiñosa Boba
Other common names: Common Noddy, Noddy Tern

Taxonomy. *Sterna stolida* Linnaeus, 1758, Jamaica, West Indies.
Race *plumbeigularis* possibly inseparable from *pileatus*. Racial separation of birds from Madagascar is not warranted. Birds from Desaventurados Is (Chile) may represent an undescribed race. Five subspecies currently recognized.

Subspecies and Distribution.
A. s. plumbeigularis Sharpe, 1879 - S Red Sea and Gulf of Aden.
A. s. pileatus (Scopoli, 1786) - Seychelles and Madagascar E to N Australia, Polynesia, Hawaii, and Easter I, and possibly this race in Desaventurados Is.
A. s. galapagensis Sharpe, 1879 - Galapagos.
A. s. ridgwayi Anthony, 1898 - W Mexico (including Socorro I, Tres Marias and Isabella, Nayarit) and W Central America (including Cocos I).
A. s. stolidus (Linnaeus, 1758) - Caribbean and S Atlantic islands (including Trinidade, Ascension, St Helena, Tristan da Cunha, Inaccessible), and Gulf of Guinea to Cameroon.

Descriptive notes. 38-45 cm; 150-272 g (average 173 g Pacific, 186 g West Indies); wingspan 75-86 cm. Dark chocolate brown noddy, with pale grey crown, sometimes almost white on forehead; narrow incomplete white eye-ring; upperwing shows slightly paler band across greater coverts; primaries black, and long wedge-shaped tail blackish; iris dark brown; bill, legs and feet black or blackish brown. Resembles *A. minutus*, but is not so dark and has shorter but thicker bill; also utters unique low, growling notes, and feeding flocks give sharp "eyeak" notes. Female significantly smaller and lighter in weight than male. Non-breeding adult similar; long period of moult continues into breeeding season. Juvenile similar to adult, but with brown crown and pale fringes to upperpart feathers. Races differ in size and in general colour tone; *galapagensis* darkest, almost blackish, with more or less distinct pale

grey superloral stripe; *pileatus* has forehead and crown bluish grey rather than ashy white; *ridgwayi* similar to latter, but slightly darker.

Habitat. Pantropical and subtropical islands, often with small populations dispersed throughout many inshore and oceanic islands. Almost inaccessible islands and coral reefs (off Somalia). Nests on cliffs, and offshore stacks (Ascension, Culebra); sometimes on ground or in tree. When resting, settles on buoys, flotsam, ships and even on the sea.

Food and Feeding. Small fish and squid. At Kiritimati (Christmas I, Pacific), about half of food in volume was fish (7-16 cm), mainly Exocoetidae and Scombridae. In Hawaii, 354 food samples contained 50 prey species. In some studies, squid comprise c. 38% of diet. Feeds mainly by hover-dipping and contact-dipping; regularly foot-patters at surface, rather than swooping; usually does not plunge-dive. Captures flying-fish in air. In Galapagos steals fish from Brown Pelicans (*Pelecanus occidentalis*). Often associates with other birds over schools of predatory fish. Forages on moonlit nights. Feeds up to 50 km from colony.

Breeding. Nests all months in Galapagos, but fewest eggs Aug-Oct; may breed at less than annual intervals (Galapagos, Ascension); aseasonal in Hawaii, but mainly Jan-Feb; Feb in Laccadives, Feb-Mar in Trinidad, Apr-May in Dry Tortugas, Apr-Aug in Seychelles; May-Jun in NE South America, Jun-Jul in Polynesia, Oct-Apr on Great Barrier Reef, Nov in Tanzania, Dec on Ponapé. In Seychelles, breeding highly synchronous on Aride and Cousin, but not on Bird I. Colonies very dense or more open, depending on available ledges; occasionally nearly solitary; few colonies of 1000's. Nest-site variable, from flat beaches to cliffs, from bare ground to low bushes and tall trees: on Dry Tortugas from 10 cm to 10 m above ground, usually not directly on ground; in Indian Ocean, on rock shelf, bare shingle and in coconut palm (*Cocos*) or *Pandanus*; in Seychelles, almost exclusively in planted coconut palms, and formerly in *Scaevola* and *Tournefortia* bushes. Nest flimsy or bulky, of seaweed and/or twigs or sticks; sometimes no material, or just small layer of debris; at Los Roques (Venezuela), bulky stick nest 1-8 m up in mangroves. 1 egg; incubation 28-37 days (mean 35-36 days); chick white or charcoal grey, with few intermediates, proportion of morphs varying among colonies (35% white Dry Tortugas, 44% Culebra); fledging c. 8 weeks. Recorded longevity of 25 years.

Movements. Poorly known. Seldom seen on or close to shore away from breeding colony. Present most of year at most tropical colonies, but seasonally absent at subtropical ones. Disperses to sea after breeding. No known directed movement.

Status and Conservation. Not globally threatened. Innumerable small to medium-sized colonies, with few exceeding 1000 pairs. World population 300,000-500,000 pairs. About 93,000 pairs in Hawaiian Is, including 30,000 on Nihoa. Caribbean population estimated at 28,000 pairs, plus possibly 50,000 in Bahamas. At least 100,000 pairs in Australian waters, including c. 76,000 in Pelsart Is (W Australia) in 1986. Very large concentrations in Phoenix and Society Is, with 10,000-100,000 in each. Some populations are increasing under protection (e.g. Dry Tortugas), and some range expansions; recently nested in New Zealand (1991). Some populations, however, are vulnerable; dwindling 500-pair colony on Ascension I is threatened by rats and cats. Christmas I (Indian Ocean) population stable, estimated at 5500 birds.

39. Black Noddy

Anous minutus

French: Noddi noir **German**: Weißkopfnoddi **Spanish**: Tiñosa Menuda
Other common names: White-capped Noddy

Taxonomy. *Anous minutus* Boie, 1844, Raine Island, Australia.
Forms superspecies with *A. tenuirostris*, with which sometimes considered conspecific. Seven subspecies recognized.

Subspecies and Distribution.
A. m. worcesteri McGregor, 1911 - Cavilli I and Tubbataha Reef (Sulu Sea).
A. m. minutus Boie, 1844 - NE Australia and New Guinea to Tuamotu Is.
A. m. marcusi (Bryan, 1903) - Marcus I and Wake I through Micronesia to Caroline Is.
A. m. melanogenys G. R. Gray, 1846 - Hawaiian Is.
A. m. diamesus (Heller & Snodgrass, 1901) - EC Pacific at Cocos I and Clipperton Is.
A. m. americanus (Mathews, 1912) - Central America and Venezuelan islands; recently found and possibly nesting off Yucatán, Mexico, and in Lesser Antilles.
A. m. atlanticus (Mathews, 1912) - Atlantic islands (St Paul, Fernando de Noronha, Ascension, St Helena, formerly Inaccessible) N & E to Gulf of Guinea.

Descriptive notes. 35-39 cm; 98-144 g; wingspan 66-72 cm. Very dark noddy with pale crown; iris brown, bill black, legs brown. Smaller and slimmer than *A. stolidus*, with subtly blacker body and greyer tail; head with more extensive white, and proportionately longer, more slender bill. Distinguished from *A. tenuirostris* by darker sooty black body, and more abruptly demarcated white forehead and pale crown. Voice also distinctive, "tik-tikoree" and staccato rattle. Non-breeding adult identical to breeding adult. Juvenile has more obvious white on head than juvenile *A. stolidus*, but more obscure pale fringes above. Races differ only slightly, mainly in plumage tone and in size; *atlanticus* has darker tail; *melanogenys* has dull yellowish orange legs.

Habitat. Oceanic and offshore islands. Breeds on sea cliffs, e.g. at Ascension and Hawaii; also on trees and bushes, e.g. in Pacific and Australia.

Food and Feeding. Almost exclusively fish, particularly small Atherinidae; lesser amounts of squid, and small amounts of crustaceans. At Ascension predominantly fish (mostly Blennidae, Holocentridae, Exocoetidae), with squid present in 12% of regurgitation samples. In Hawaii 90% fish (of 18 families), and 10% squid; mainly Synodontidae and Mullidae and squid (Ommastrephidae) in NW Hawaii. In Australia mainly anchovy (*Engraulis australis*). Feeds by hover-dipping and contact-dipping; foot-patters. Flocks of 5000 and more gather quickly over shoals of fish. May feed up to 80 km from breeding colony.

Breeding. Mostly annual cycle: Mar-May in Hawaii, May in Venezuela, Jun-Jul at Ascension, Oct-Nov in Australia; but in Fiji Jun in some years, Sept in others (possibly a secondary peak of failed breeders). Colonies often dense. Nest in trees and bushes where available, usually a platform of seaweed and/or twigs and leaves cemented by excrement, quite distinct from bulky stick nest of *A. stolidus*; collects nest material in flight by contact-dipping. In Australia nests up to 15 m up in *Pisonia grandis*, but favours *Ficus* and *Celtis* when available; in *Cecropia* on Cocos I (Costa Rica); in Belize and in Los Roques (Venezuela), 4-10 m up in mangroves. Larger trees hold proportionately more nests, but species shuns largest trees. Where no trees, nests on ledges on sea cliffs (e.g. Ascension, main islands of Hawaii). 1 egg; prolonged incubation 30-37 days; chick blackish with whitish forehead; fledging c. 48-60 days; returns to nest to be fed for several weeks; chicks that fall from nest are abandoned. In French Frigate Shoals (Hawaii) regularly double-brooded, laying second egg while feeding first fledgling at nest; successful in c. 50% of cases.

Movements. Poorly known. Permanent resident around some islands (e.g. Hawaii, Ascension). Partial dispersal from others; from Fiji, some birds disperse up to 2900 km W through Solomon Is. High degree of racial variation suggests species is generally sedentary, with isolated populations.

Status and Conservation. Not globally threatened. Total population over 200,000 pairs, including 10,000 on Ascension I and 20,000 in Hawaii. Largest concentrations in Line Is and Phoenix Is, with 10,000-100,000 pairs in each. In Australia, logarithmic growth at Heron I (Capricorn Group) since first nests in 1920, to 40,000 in 1985. Many local populations, however, vulnerable; extirpated from Malden I (Line Is) due to destruction of vegetation by goats. Cyclones occasionally interfere with parental feeding, causing chick starvation; occasionally subject to massive starvation, as at Ascension I in Jul-Oct 1958, when many young died. On some islands, young birds are trapped by sticky seeds of *Pisonia*, which form dense mats in some years.

Bibliography. 40. Lesser Noddy

Anous tenuirostris

French: Noddi marianne **German**: Schlankschnabelnoddi **Spanish**: Tiñosa Picofina

Taxonomy. *Sterna tenuirostris* Temminck, 1823, Senegal; error = Seychelles.
Forms superspecies with *A. minutus*; further study may even show the two to be conspecific. Two subspecies recognized.

Subspecies and Distribution.
A. t. tenuirostris (Temminck, 1823) - Seychelles, Mascarene Is, and probably Maldives, with possible breeding attempts having taken place in Somalia; non-breeders visit Arabia, Madagascar and rarely Tanzanian coast.
A. t. melanops Gould, 1846 - Houtman Abrolhos Is (Western Australia), and formerly Indonesia.

Descriptive notes. 30-34 cm; 97-120 g; wingspan 58-63 cm. Blackish brown, with whitish forehead and crown blending into more ashy grey hindcrown and nape; lores whitish; sides of neck and throat sooty; iris dark brown, bill black, legs brownish black. Very similar to *A. minutus*, but smaller and paler, with pale (not dark) lores; pale of head blends more evenly into dark of neck. Juvenile paler brown, but also has white cap. Race *melanops* similar to nominate, but with blackish stripe above eye extending onto lores.

Habitat. Oceanic islets. Nests in trees, occasionally in bushes.

Food and Feeding. Small fish and invertebrates. Feeds by hovering and aerial- or contact-dipping. Associates with *A. stolidus*.

Breeding. Aug-Oct. Sometimes congregates in large colonies; 5000 pairs on Lizard I (Mauritius), up to 30,000 pairs in Pelsart Group (Houtman Abrolhos). Some colonies stable, others shift from year to year. On Cousin and Aride (Seychelles), builds bulky nests 5 m apart in tall trees, occasionally in low bushes. In Houtman Abrolhos, substantial platform of brown algae and excreta on mangroves; nests often close together, only 30 cm apart. 1 egg; incubation and fledging periods not documented, but incubation probably c. 35 days; incubating adult tolerates close approach; chicks that fall from nest are not fed.

Movements. Permanent resident around Pelsart Group. Other movements not known, but species occurs fairly regularly outside breeding season off E Africa.

Status and Conservation. Not globally threatened. Few colonies have been discovered to date. Abundant in Western Australia until about 1900, then unexplained disappearance of large colonies; recovery in mid-20th century, and now apparently stable, with estimates of 27,000 nests in late 1960's and 30,000 in 1986. Size of Indian Ocean populations not known. Some colonies are apparently vulnerable.

Genus *PROCELSTERNA* Lafresnaye, 1842

41. **Blue Noddy**

Procelsterna cerulea

French: Noddi bleu **German**: Blaunoddi **Spanish**: Tiñosa Azulada
Other common names: Blue Ternlet; Blue-grey Noddy/Ternlet (superspecies)

Taxonomy. *Sterna Cerulea* F. D. Bennett, 1840, Kiritimati (Christmas) Island, Pacific Ocean.
Forms superspecies with *P. albivitta*, with which often considered conspecific, but significant differences in size, coloration and geographical range; the two are sometimes incorrectly treated as pale and dark morphs of same species; some authors have claimed that races *skottsbergii* and *imitatrix* of *P. albivitta* belong to present species, but specimen evidence refutes this. Internal taxonomy confused at present, with much overlap of forms, e.g. birds from Society Is significantly darker than those from Tuamotu Is, and might not be referable to same race; validity of races and their distributions require careful systematic revision based on known breeding specimens, but these are lacking from various parts of its range. Emendation of species name to *caerulea* is unjustified. Five subspecies currently recognized.
Subspecies and Distribution.
P. c. saxatilis W. K. Fisher, 1903 - Marcus I and N Marshall Is E to NW Hawaiian Is.
P. c. nebouxi Mathews, 1912 - Tuvalu (Ellice Is) E to Phoenix Is and S to Fiji and Western Samoa.
P. c. cerulea (F. D. Bennett, 1840) - Kiritimati (Christmas) I in Line Is, and also Marquesas Is.
P. c. teretirostris (Lafresnaye, 1841) - Tuamotu Is, and probably this race likewise in Cook, Austral and Society Is.
P. c. murphyi Mougin & de Naurois, 1981 - Gambier Is.

Descriptive notes. 25-28 cm; 41-69 g (average 45·4 g, but non-breeders significantly lighter); wingspan 46-60 cm. Distinctive pale noddy, with relatively short, slender black bill and short, slightly forked tail; all-grey head and body, with only slightly paler underparts; white partial spectacle behind eye and small black spot in front; upperwing has slightly darker grey or brown-tinged coverts, and blackish primaries; below, shows little contrast between primaries and underwing-coverts; eye brownish black; bill and legs black. Smaller than *P. albivitta*, which is also paler grey above, and white below and on head. Races differ mainly in plumage tone, but some confusion exists; nominate *cerulea*, at least in Marquesas, apparently darkest; *teretirostris* has paler head and underparts, but is significantly paler in Tuamotu Is than in Society Is.
Habitat. Tropical oceanic islands. Breeds on cliffs or rocky areas. Forages over lagoons and inshore waters.
Food and Feeding. Has narrowest gape of any tern, and takes tiniest fish (average length 17 mm; mainly larval Synodontidae, Exocoetidae, Mullidae, Bothidae), squid, crustaceans, and pelagic sea striders (*Halobates sericeus*, *H. micans*); proportions vary seasonally and geographically. Fish present in 97% of samples, and squid in 50%. At Kiritimati over 50% of food items (75% of food volume) fish, with squid and crustaceans equally represented. At sea, species is the only primarily insectivorous pelagic tern. Usually feeds in small groups close inshore at breeding islands. Flies low over water with quick shallow wingbeats, dipping to surface to snatch tiny prey; often hovers low, foot-pattering on surface. Adults do not carry fish in bill.
Breeding. In Hawaii reported to breed throughout year, with laying peak Feb-Mar, few nests in May, Aug, Nov, hence probably an asynchronous spring breeder, rather than truly aseasonal; Aug-Nov at Kiritimati, and Jun-Aug in Phoenix Is. Loose colonies of up to 100 pairs on islets in lagoons. Nests on rocky substrate using crevice, ledge or concavity in cliffs or rock crops, or on gravel or coral rubble, usually on slopes; also under coral slabs or vegetation, seldom fully concealed; nest generally inaccessible to most predators. Usually no material, but may assemble a few shells, bones, feathers or stems around egg. Clutch 1 egg; incubation period not known; chick uniform whitish, with black bill and eye; hatching weight under 10 g; fed by regurgitation, and brooded continuously for 2-3 weeks. Productivity estimated at 0·5 young/pair on Nihoa (Hawaii); some eggs predated by Nihoa Finch (*Telespyza ultima*). Age of first breeding not reported, but some may breed at 1 year where nest-sites not limiting. Recorded longevity of 11 years.
Movements. Not known. Usually remains close to breeding colonies.
Status and Conservation. Not globally threatened. Censuses in small part of range gave at least 30,000 pairs, and overall total for species may be closer to 100,000 pairs. In NW Hawaii, 4000 pairs plus 8000 non-breeders. Up to 10,000 pairs each in Line and Phoenix Is; up to 1000 in Gambier Is, 2000 on Kiritimati. Difficult to census owing to inaccessible sea-cliff nesting sites, which protect species from egging and predators in most places. Cliff nesting habitat is a limiting factor. The colony on Kaula I (Palmyra, Line Is) was eliminated when the island was used for a bombing range.

S. (1984a, 1990), Harrison, C. S. *et al.* (1984), Holyoak & Thibault (1984), Mougin & de Naurois (1981), Munro (1960), Murphy (1936), Muse & Muse (1982), Pratt *et al.* (1987), Rauzon *et al.* (1984).

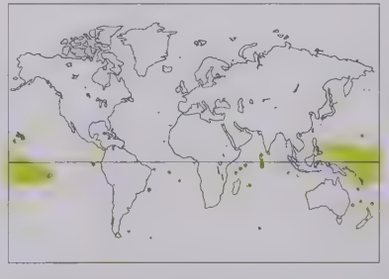
42. **Grey Noddy**

Procelsterna albivitta

French: Noddi gris **German**: Graunoddi **Spanish**: Tiñosa Gris

Taxonomy. *Procelsterna albivitta* Bonaparte, 1856, Lord Howe Island.
Temperate and subtropical counterpart of *P. cerulea*, with which it forms a superspecies; sometimes considered conspecific. Some authors have claimed that races of SE Pacific belong to *P. cerulea*, but specimen evidence refutes this. Three subspecies recognized.
Subspecies and Distribution.
P. a. albivitta Bonaparte, 1856 - Lord Howe I, Norfolk I, Kermadec Is and Tonga.
P. a. skottsbergii Lönnberg, 1921 - Henderson I, and Easter and Sala y Gómez Is.
P. a. imitatrix Mathews, 1912 - San Ambrosio and San Félix (Desaventurados Is), off C Chile.
Descriptive notes. 28-31 cm; wingspan 46-60 cm. Small, relatively long-legged noddy, with grey back, darker grey wings and tail, and pale greyish to whitish head and underparts; white or pale

underwing-coverts; eye with narrow black semi-circle at front, white behind; iris brown, bill black; legs and feet blackish brown, with pinkish yellow webs; mouth-lining yellow. Distinguished from slightly smaller *P. cerulea* by paler plumage, with much whiter head and underparts. Juvenile tinged brownish above, but uniform, without scaling or barring. Races differ mainly in plumage tone; underparts whitest on *skottsbergii* and *imitatrix*.
Habitat. Temperate and subtropical oceanic islands. Breeding birds occur around coasts of rocky islands, nesting on cliffs up to 600 m high, or on ground. Forages in inshore waters.
Food and Feeding. At Desaventurados Is (Chile) takes tiny crustaceans, and also fish and squid; small crustaceans at Kermadec Is and Lord Howe I. Feeds by fluttering or hovering low over water, and repeatedly dipping; does not foot-patter. Seen to face upwind, and at end of food patch circle back to beginning.
Breeding. Aug-Nov in SW Pacific; at Easter I present in Dec, but not nesting. Reported to be only passively colonial. Nest in cliff crevice or ledge, or on ground under rocks, on bare rock, or under vegetation such as tussock grass (Kermadecs). 1 egg; incubation period unknown; chick uniform smoky grey or chocolate brown, unspeckled, with dark felted forecrown, and paler belly, nape and face; pin feathers appear c. day 17; fledging 32-45 days. Some may be double-brooded.
Movements. Non-migratory; disperses around breeding colony, but rarely reaches continental waters. Uncommon visitor to N New Zealand, with flocks of 1000 in Jan 1970; non-breeders reported in many parts of S Pacific. Straggler to E Australia.
Status and Conservation. Not globally threatened. Total population probably under 25,000 pairs, most in SW Pacific. Norfolk I holds several thousand pairs, possibly up to 10,000; under 10,000 pairs in Kermadecs, where said to be common, with several thousand pairs on Herald Islets; fewer than 1000 pairs on Lord Howe I. Status not at all well known, and species possibly rare. The two SE Pacific subspecies are probably endangered: Easter I population is threatened by cats; only about 40 birds documented on Desaventurados, but no recent data. Cliff-nesting assures some survival, even on predator-infested islands.
Bibliography. Eller (1989), Falla (1970), Falla *et al.* (1981), Flegg & Madge (1995), Hermes (1985), Holyoak & Thibault (1984), Johnson (1967), Lindsey (1992), Marchant & Higgins (1996), Merton (1970), Morris (1972), Mougin & de Narois (1981), Murphy (1936), Oliver (1974), Pizzey & Doyle (1980), Robertson (1985), Schodde *et al.* (1983), Simpson & Day (1994), Slater *et al.* (1989), Soper (1969a, 1976), Tarburton (1981), Trounson (1987).



Genus *GYGIS* Wagler, 1832

43. **White Tern**

Gygis alba

French: Gygis blanche **German**: Feenseeschwalbe **Spanish**: Charrán Blanco
Other common names: Fairy Tern(!); Common White Tern (*alba*); Little White Tern (*microrhyncha*)

Taxonomy. *Sterna alba* Sparrman, 1786, Ascension Island.
Placed in a monotypic genus, owing to unique plumage and bill. Race *microrhyncha* sometimes separated as distinct species, but apparently interbreeds with *G. alba* in Kiribati. Internal taxonomy extremely confusing, with correct subspecific allocations and limits frequently unclear and disputed; some authors have preferred to recognize several additional races, including *royana* of Norfolk I and Kermadec Is, *pacifica* of Caroline Is, Melanesia and other islands of S Pacific, and *rothschildi* of Hawaii, all of which herein included in nominate race, but all are sometimes referred instead to race *candida*. Birds of Seychelles and Mascarenes described as *monte*, but not separable from *candida*. Four subspecies currently recognized.
Subspecies and Distribution.
G. a. alba (Sparrman 1786) - Caroline Is through Melanesia to Norfolk I and Kermadec Is; Hawaii; W Mexico (Clipperton), Costa Rica (Cocos I) and probably Colombia (Malpelo); S Atlantic islands (Fernando de Noronha, Trinidade, Ascension, St Helena).
G. a. candida (Gmelin, 1789) - Seychelles and Mascarenes through Indian Ocean to SC Pacific, including Marquesas Is (Hatutu).
G. a. microrhyncha Saunders, 1876 - Marquesas Is (Eiao to Fatu Hiva) and apparently also Phoenix and Line Is.
G. a. leucopes Holyoak & Thibault, 1976 - Henderson I and Pitcairn I (SE Pacific).

Descriptive notes. 25-30 cm; 92-139 g; wingspan 76-80 cm. Most ethereal of seabirds; entire plumage immaculate white, with black ring around eye and dusky flight-feather shafts; unique black bill slightly upcurved, and tapering to point; legs blackish to dull bluish; short tail with slight fork; buoyant and erratic flight with deep, slow wingbeats. Juvenile white, with black mark behind eye, grey hindneck, brownish grey back and scapulars, and some black edges to remiges. Races differ mainly in colour of remex shafts, and soft parts: *alba* and *microrhyncha* have slimmer, straighter, all black bill and paler primary shafts; *microrhyncha* also has paler legs and feet; *candida* has blue-grey base to noticeably up-angled bill, and dark primary shafts; *leucopes* often has creamy white legs.
Habitat. Coral islands, usually with vegetation. Nests in trees and bushes, and on rocky slopes and cliffs; also on artificial substrates.
Food and Feeding. Mainly small fish, occasionally squid and crustaceans. At Kiritimati (Christmas I, Pacific), fish and squid taken equally, and 22 fish families represented; adults ate mainly Blennidae, mostly smaller than 2 cm, but fed chicks mainly halfbeaks (Hemiramphidae) 1-8 cm long. In Hawaii c. 85% fish and 14% squid. Carries 1-6 fish neatly arranged in bill to young. Catches prey by diving to water surface.

Breeding. Mar-Sept with peak Apr-May in Hawaii, May-Aug at Kiritimati and Chagos Is; in Maldives intermittently throughout year; in Seychelles, throughout year on Cousin I but apparently absent after Jan on Bird I. Nest-spacing varies with nest-site availability; in Seychelles 1 nest/180 m². Unique nesting habit: lays single egg on bare branch, usually in slight depression at a fork or on midrib of palm frond or banana leaf. Nest height 0-20 m; branch width 8-25 cm. On Bird I, only on *Casuarina* trees or on buildings (former site secure from rats, latter subject to heavy predation on eggs and chicks). On Ascension 10% nest in cliffs. Where sites scarce (Ascension), successive pairs occupy same site. In other cases the same pair re-lays after losing egg. On most islands no ground predators apparent. Tree-nesters sit tighter, not flushing until observer within 2 m; those on rock flush sooner. Eggs and chicks often blown from nest, particularly from smooth-limbed *Casuarina*. Clutch 1 egg; incubation 30-41 days (average 34-36); chick white, with strong claws with which it clings to branch. Hatching success 35-45%. Recorded longevity of 17 years.
Movements. Resident all year round on some islands, seasonal visitor on others. Outside breeding season lives at sea, but movement patterns not known.
Status and Conservation. Not globally threatened. World population unknown, but exceeds 100,000 pairs. A very widespread species on tropical islands, although absent from many apparently suitable islands. Largest concentrations in Western Samoa, Tokelau, Line Is and Phoenix Is, each with more than 10,000 pairs.
Bibliography. Genus *LAROSTERNA* Blyth, 1852

44. **Inca Tern**

Larosterna inca

French: Sterne inca **German**: Inkaseeschwalbe **Spanish**: Charrán Inca

Taxonomy. *Sterna Inca* Lesson, 1827, Lima, Peru.
Unique among terns in morphology, appearance, habitats and habits, and unquestionably warrants segregation in monospecific genus. Monotypic.
Distribution. Humboldt Current region from N Peru (Lobos de Tierra I) S to C Chile (S at least to R Aconcagua).

Descriptive notes. 39-42 cm; 180-210 g (in captivity, average 189 g). Unique and unmistakable; body dark slate, paler on throat and underwing-coverts; white stripe curling back and downwards from gape to side of neck, where it fans out into long satiny feathers; trailing edge of wing white, and white edges to four outer primaries; iris brown, bill and legs dark red; yellow bare area or wattles at base of bill; wing shape rounded, and tail moderately forked; has characteristic fluttering flight, with rapid wingbeats; serrated flange on middle toe unique among terns. Juvenile uniform blackish, with small grey tufts at base of bill. Subadult has brown cast, and dark horn-coloured bill which reddens with age; curling gape plumes dull brownish.
Habitat. Mainly found on inshore "guano islands", but also 67 km offshore on Hormigas de Afuera I; typically along rocky coasts, or where sandy beaches are backed by cliffs. Nests on rocky sea cliffs and guano islands, also in artificial structures.
Food and Feeding. Mainly small anchovetta (*Engraulis ringens*); also planktonic crustaceans; offal and scraps. Associates with fishing boats; large flocks (average 100+ in C Peru) attend fishing activities, including dynamiting. Rapidly detects a surfacing sea lion, and is the most numerous species associating with these mammals. Feeding flocks number up to 5000. Forages mainly by plunge-diving, and contact- and surface-dipping; scavenges for scraps left by sea lions and avian predators.
Breeding. Probably aseasonal. Eggs found Apr-Jul and Oct-Dec; young found mid-Jul. Nests in fissures, burrows and small caves, in troughs in guano or sand, and at base of or under rocks and boulders on island slopes; in abandoned petrel burrows or at entrance of penguin burrows; also on ledges in and under buildings and piers. Many nest on abandoned dredges and barges in harbours. Often with Peruvian Diving-petrel (*Pelecanoides garnotii*) or Red-legged Cormorant (*Phalacrocorax gaimardi*). Where vultures present, nests more hidden; sometimes forced to abandon breeding attempt when other seabirds begin nesting. 2 eggs, sometimes 1, usually well hidden in tunnel or crevice; incubation period not reported; chick dark grey above, paler grey below, with faint speckling on head; fledging c. 4 weeks; fully dependent for at least 1 month further, during which practises foraging techniques.
Movements. Permanently resident, with no systematic migration. Non-breeders move opportunistically to follow food. Some disperse N to Ecuador.
Status and Conservation. Not globally threatened. Numbers fluctuate from year to year, depending on food availability in relation to El Niño (see Volume 1, page 341); populations decline greatly during severe occurrences of El Niño, but rebound quickly, suggesting mass emigration rather than mass starvation; total population estimated to vary around c. 50,000 pairs. Main abundance on C coast of Peru among inshore guano islands, particularly Chinchas, Pescadores and Asia Is. Formerly considered present in enormous numbers, but neither as abundant, nor as vulnerable, as the typical guano species. Main nesting habitat is not limited. Formerly confined to coastal Peru; first bred in Chile during late 1930's, and is now common S to Valparaíso.
Bibliography. Anon. (1994h), Ashmole & Tovar (1968), Blake (1977), Bruning & Clare (1977), Duffy (1983), Duffy *et al.* (1984), Duquet (1995), Guillen (1988), Hellmayr & Conover (1948), Hilty & Brown (1986), Johnson (1967), Koepcke (1970), Meyer de Schauensee (1982), Moynihan (1962), Murphy (1936), Parker *et al* (1982), Ridgely & Gwynne (1989), Rivadeneira *et al.* (1986), Schlatter (1984), Tovar (1968).

Class AVES

Order CHARADRIIFORMES

Suborder LARI

Family RYNCHOPIDAE (SKIMMERS)

- Medium-sized rather aerial waterbirds, with long, pointed wings and short legs; unique bill structure, with very narrow lower mandible much longer than upper.
- 36-46 cm.

- Pantropical, extending to subtropics and marginally into temperate zone.
- Large rivers and other water bodies, mainly inland.
- 1 genus, 3 species, 5 taxa.
- 1 species threatened; none extinct since 1600.

Systematics

In the absence of any known fossil of Rynchopidae, estimates of the phylogenetic history of the skimmers are based entirely on the comparative anatomy, behaviour and molecular make-up of extant species. Anatomists of the nineteenth and early twentieth centuries established the skimmers within the order Charadriiformes and the suborder Lari, which also includes the skuas, gulls and terns. The three extant species of Rynchopidae are included in a single genus, *Rynchops*, because all share a unique foraging behaviour and its associated structural adaptations, and they closely resemble each other in plumage pattern.

Recent publications that are based on myology, osteology, behaviour and molecular data, and analysed by phylogenetic methods, agree that the gulls (Laridae) and the terns (Sternidae) are more closely related to each other than either group is to the skimmers. However, questions about the relationships among terns have been raised, and one author concluded that the noddies (*Anous*, *Procelsterna*) are more closely related to skimmers than to "true" terns; in addition, there are some who disagree about the precise placement of the skuas within the suborder Lari. To date, studies of the Lari have been incomplete in their coverage of genera, and have differed somewhat in the taxa covered. Until we have corroborative results from different kinds of data covering all of the genera, such problems must remain unsolved.

Several fossils have been referred to Sternidae and Laridae, but all those identified as terns are suspect. Since the oldest of the gull-like fossils are from the Eo-Oligocene deposits of France, we may infer that the origin of the skimmer and larid lines occurred at an earlier stage, perhaps in the early Eocene.

The family covers a wide geographical area, with the Indian Skimmer (*Rynchops albicollis*) occurring in southern Asia, the African Skimmer (*Rynchops flavirostris*) throughout much of Africa, and the Black Skimmer (*Rynchops niger*) in North, Central and South America. The South American races *cinerascens* and *intercedens* have on occasion been considered to constitute two additional species, but current opinion suggests that the New World forms should be treated as a single species with three subspecies. More information is required from the northern part of the Santa Fé Province, Argentina, where the races *cinerascens* and *intercedens* appear to meet without intergradation.

The birds of South America and Asia are mainly restricted to large rivers and estuaries, and those of Africa to large rivers and lakes. North American birds are atypical in their dependence on sandy coasts and barrier islands. Nevertheless, most of our knowledge of the biology of skimmers applies to the North American Black Skimmer. Studies on African Skimmers and the few data available for the Indian Skimmer suggest that their biology and behaviour closely match those of the Black Skimmer except for some details related to their distinctive environments.

Morphological Aspects

Skimmers compare in size with medium-sized to large terns, or medium to small gulls, and they have a wingspan ranging from 102 to 127 cm. Size designations are complicated by pronounced sexual dimorphism, with males notably larger than females in the American and Asian species, while the African Skimmer is the smallest and least dimorphic of the three.

Adult skimmers are striking and conspicuous. The plumage is largely blackish above and pure white below, the bill mainly orange-red, and the feet red. Seasonal changes are minor apart from the acquisition of a white collar during the non-breeding season in the Black and African Skimmers. Young birds are much less conspicuous and handsome than the adults, as juvenile plumage is brown above, mottled or scalloped with buff or whitish. The well camouflaged downy chicks are sand-coloured, flecked with black.

Adult birds undergo two moults yearly, a complete moult after breeding and a body moult prior to breeding. Moult of the flight-feathers is protracted and may overlap the pre-breeding moult to some extent. Birds of the year resemble adults in most respects within about six months of fledging, but juvenile wing-coverts and brownish crown feathers take longer to be replaced.

Skimmers seem front-heavy because of the long, deep bill and large head, and a tail that is not correspondingly enlarged. The appearance in flight or on the ground is distinctive and not particularly gull-like or tern-like, while their foraging behaviour is unique (see Food and Feeding). When foraging they fly low over the water with the mouth open and lower mandible partially submerged, whence the name "skimmer". A skimmer's flight is usually relaxed and graceful, and the long, pointed wings beat slowly for the size of the bird. Wingbeats during skimming are shallower and more rapid, but in a favourable wind the birds may glide for considerable distances with the wings raised about 40° above horizontal. The proportionally long outer primaries extend far beyond the tip of the tail when the wings are folded.

The three skimmer species are unmistakable birds that seem somehow strangely proportioned on account of the very long, pointed wings, the heavy head and the long bill. By far the most arresting feature is the oddly shaped mainly bright red bill, the lower mandible of which is much longer than the upper and extremely thin towards the tip, both specialized developments related to the remarkable method of foraging. The slightly smaller size, the colour of the bill tip, and the lack of a white collar in breeding plumage are the best features for differentiating the African Skimmer from its two allopatric congeners.

[*Rynchops flavirostris*, Okavango, Botswana. Photo: Wendy Dennis/ Planet Earth]

The legs are intermediate in length between those of terns and gulls, and the three front toes are connected by incised webs. The webbing on the toes may help to support the bird when it is standing on soft sand or mud, and it probably also assists in some forms of thermoregulation behaviour (see General Habits). Skimmers sometimes wade, but they do not swim, dive or plunge into water.

The most curious feature of a skimmer is its bill, in which the mandibles are strikingly different in size and shape. Both are streamlined to plough through water with little resistance. The upper mandible is laterally compressed toward the tip, but more inflated and oval in transverse section near its base; overall, it is slightly down-curved, and is pointed at the tip. Its ventral, or lower, surface is very narrow, but broadens abruptly towards the mouth. The lower mandible, after a similar widening for the mouth, becomes even more compressed into a vertical, knife-like blade, and this extends forward approximately 1-3 cm beyond the tip of the upper mandible. When seen from above or below it is extremely thin, but from the side it appears deep and blunt-tipped. Many low, parallel ridges obliquely cross each side of the mandibular blade. The mouth opening is broad, while the tongue is short and does not extend to the streamlined mandibles. When the jaws are closed the knife-edge of the lower mandible fits into a narrow groove on the upper, but a greater curvature of the upper tomia often leaves a slight gap near the middle of the closed bill in lateral view. Despite the protruding rhamphotheca, or horny covering, of the lower jaw, its bony core is only slightly longer than that of the upper jaw. Interestingly, the laterally compressed mandibles of the unfledged chick are of nearly equal length, and both are pointed. The significance of the skimmer's odd bill structure is closely related to its remarkable method of foraging (see Food and Feeding).

Unlike most through gulls and terns, skimmers are active at night, often flying and calling in flocks, and feeding from dusk until dawn. Correspondingly, the skimmer's eye has an unusually large maximum pupillary opening. In order to protect the retina in the brilliant daylight reflected by white sand beaches and their aquatic environs, the circular pupil closes to a narrow, vertical slit, a unique adaptation among birds. The slit provides a greater reduction of the pupil than is possible with a circular sphincter.

Habitat

Skimmers frequent the edges of salt, brackish or fresh water in tropical to temperate zones, mostly at altitudes from sea-level up to about 450 m on larger rivers, but sometimes much higher on lakes. In the non-breeding season, their lives consist largely of alternating periods of foraging and resting. Most foraging is done in calm, shallow water without emergent vegetation; because skimmers forage most effectively where prey are concentrated, such habitat must be extensive to guarantee location of suitable foraging conditions daily. Isolated, open beaches, sandbars and mudflats are preferred for both roosting and breeding, although some Black Skimmers also breed on flat mats of vegetation in salt-marshes. Such habitats and conditions are found mainly on coasts with barrier islands, on large rivers that experience extensive periods of high and low water, and on some inland lakes. Man-made habitats may also be used (see Status and Conservation).

In coastal areas, tides influence fish concentrations. During flood tide, myriads of fish crowd along the edge of the advancing water to gain access to marshy areas left dry at low tide, and the Black Skimmer forages regularly in salt-marsh channels. The ebbing tide leaves shallow, temporary or permanent tidal pools, in which fish and shrimps are trapped. Different studies have found peak skimming activity to occur at different tidal stages, but middle and low tides are apparently favoured.

Skimmers sometimes feed in deeper water on schools of fish, such as mullet (*Mugil*), that are near the surface. They also catch fish in the thin sheet of water spread on the beach by breaking waves, while skimming along the beach edge for considerable distances.

Except in North America, skimmers' annual cycles are governed largely by the alternation of rainy and dry seasons, and the concomitant rise and fall of water levels of the large rivers. At flood stage, the water may rise many metres, often breaching the riverbanks, and in some areas flooding vast areas of forest. At low water, silt is deposited and sandbars are formed. These seasonal changes are somewhat analogous to the tides: concentrations of fish are stranded in pools and small lakes left by the receding water, and fish are also concentrated in the shallows of the reduced river channel. Skimmers tend to leave the rivers when

the waters run high, but find suitable breeding and roosting conditions at low water.

General Habits

Skimmers are social birds, breeding in colonies and roosting in tight groups, usually in the company of terns and other species. Foraging, however, is carried out independently of other species and may be solitary, in pairs, in family groups, or sometimes in moderate to large flocks. Groups of skimmers are more likely to maintain a tight flock in flight than are terns or gulls, sometimes performing turns and other manoeuvres with considerable synchrony, and, even when skimming, pairs or small groups may fly in formation.

When not otherwise occupied, skimmers sleep, rest or perform maintenance or comfort behaviour. They usually sleep with the head turned to one side and the bill tucked into the scapular feathers. Most birds on the periphery of large roosting flocks turn their heads toward the outside to be alert to any possible approaching danger. At the colony, one member of a pair typically stands beside its incubating mate but usually faces in the opposite direction, again maximizing their combined vigilance. All birds, both in the colony and when roosting, orientate their bodies to face into strong winds. Sometimes they lie prone on their bellies and rest the bill on the ground, and when incubating birds do this they leave a radiating pattern of lines in the sand around the nest, from the sharp, lower edge of the bill, indicating the directions in which they have faced.

Skimmers bathe in shallow water, and preen by nibbling the oil-gland and stroking the feathers between the mandibles. They yawn by opening the mouth for one or two seconds, presumably to clear the eustachian tubes. Stretching occurs with the legs flexed, the head lowered and the folded wings raised. Relief from extreme heat is typically achieved by fluttering the gular region, raising the body feathers and holding the folded wings slightly away from the body, but cooling can also be effected by dragging the webbed feet and breast feathers through water in flight.

An adult skimmer's bill can not be used effectively for pecking or grasping at the tip, although the bird can grasp objects on the ground if it first turns its lowered head sideways. This limited dexterity with the bill may explain the lack of nest building in this family. In contrast to the adults, chicks are able to peck effectively almost until they fledge (see Breeding).

Voice

Although skimmers are not raucously vocal, their calls may be heard at dusk and at night, as well as during the day. They are most vocal in the colony during aggressive interactions or upon taking flight after disturbance. The larger species give single or repeated, short calls that have been likened to the distant barking of hounds, but these barks become longer and harsher under stress; although the sexes have similar calls, those of males are lower in pitch. Calls of the slightly smaller African species are sharper, more strident and higher-pitched.

In the colony, birds call to each other at the time of nest relief, and they utter soft, liquid notes when settling on their eggs. Adults bringing fish attract the attention of small chicks by calling softly, and chicks utter soft calls when begging for food. Vocalizations of the skimmer in the colony continue through the night, when other species are silent. A chick captured in the hand or by a predator emits a shrill alarm note that usually causes other chicks crouched nearby to run away.

Food and Feeding

The foraging method of all skimmers is highly stereotyped and is unique among birds. It consists of flying along ploughing the water with the lower mandible more or less at random, in order to locate concentrations of fish and to grasp individual prey items following chance collisions. Birds typically skim a stretch of about 50-100 m, before flying up and round and skimming the same stretch again. Skimming proves to be an effective feeding method in habitats that provide consistently high densities of fish or shrimps, in shallow water or near the surface of deeper water. Because skimming is more tactile than visual it permits crepuscular and nocturnal feeding, and skimmers are known to feed intensively at dusk and even on the darkest of nights. The combined influences of nocturnal and tidal cycles on feeding activity are complicated and poorly understood.

Skimmers are sociable birds that breed in loose colonies and roost in tight huddles on sandbanks, often along with terns and other species. When feeding, they may fly in ones and twos, or perhaps in small flocks. Much of the time is spent loafing on beaches or indulging in preening or bathing activities, again communally. At rest they will always point head and body to face into the wind. Unlike gulls and terns, when flying in flocks they synchronize their movements, wheeling and turning gracefully in unison. The dark bill tip is the most obvious feature indicating that these birds are Black Skimmers.

[*Rynchops niger niger*, Long Island, New York. Photo: Tom Vezo]

The skimmer's upper and lower mandibles are different in length and shape, both compressed laterally to form a thin, streamlined instrument that enables the bird to catch prey as it flies along with the bill open and the lower jaw ploughing through the water surface. Fish are hardly ever scooped up on the lower jaw, but rather the head and the top of the neck are drooped so that the upper jaw can fasten onto the catch. When a larger fish is encountered, the head is twisted backwards under the bird, enabling both jaws to snap shut on the prey, which is then swallowed either in flight or once the bird lands. Note the very slight wake created by the skimming action of this Black Skimmer.

[*Rynchops niger*. Photo: Kevin T. Karlson]

Skimmers eat almost exclusively fish, but shrimps may be important too, particularly on the south-eastern and Gulf coasts of North America. Among the fish most important to the North American Black Skimmer are the tidewater silverside (*Menidia peninsulae*), sheepshead minnow (*Cyprinodon variegatus*), and several species of killifish (*Fundulus*) and of mullet. The prey taken are typically 4-12 cm in length, or exceptionally up to 20 cm long. Elsewhere in the world, the precise prey species of skimmers have not been well documented.

Skimmers are structurally and behaviourally adapted as "skimming machines". Newly fledged chicks instinctively attempt to skim sand dunes and beach edges as well as water, resulting in sharp downward jerks of the head. They soon learn to skim only in water, and suitable foraging habitats are learned while they accompany their parents. Skimming water does not require a disproportionately long lower jaw, but it is facilitated by the lateral compression of the mandibles. Unfledged chicks have laterally compressed upper and lower mandibles of roughly equal length, and those of newly fledged young are only moderately disparate in length. The bill reaches adult proportions within about three months of fledging. The rhamphotheca of a skimmer's lower jaw grows continuously faster than that of the upper, and this is kept in check by wear against the sandy or muddy bottom when skimming in shallow water, and by breakage upon hitting obstructions. The length and shape of the lower mandible is correspondingly variable among individuals, and over time, within individuals.

The chance of catching a fish while skimming with the tip of the lower mandible would be reduced if the upper mandible also ploughed the water. Such is usually not the case because the bird raises its upper jaw as much as 45° above the closed position by bending it at its base, a capacity of movement greater than that found in gulls and terns. If fish are to be found deeper in the water, however, the bird may submerge the entire lower jaw and part or all of the upper.

How does the bird grasp a fish if it is struck beyond the reach of the upper jaw? It is often stated that fish slide up the edge of the lower mandible during skimming. In almost every case, however, the head and the upper segment of the neck bend downward, doubling under the body in such a way that the upper mandible can reach the prey. Larger fish are withdrawn from the water with the head facing backwards, but this action is not readily observed in the field because the time to catch a fish and return the head to normal position is only a fraction of a second. Flight is uninterrupted while catching a fish, except for an extra wingbeat and a downward flick of the tail.

Fish are held crosswise in the bill, and are swallowed in flight or after landing; those intended for a mate or chick at the colony may be carried for several kilometres. The knife-edge of the lower mandible and the extremely narrow upper jaw provide little stability for carrying a flopping fish, but the grip is powerful and the mandibles dig into the fish, sometimes almost severing it in two. Additional stability is provided by the slightly decurved tomia of the upper mandible which prevent the grasped fish from sliding forward. Nevertheless, fish are occasionally dropped because of an insecure grip, or because of harrassment by gulls.

The long bill and relatively long neck permit the bird to maintain its body in position about 5 cm above the surface of the water while in the skimming posture. The wave created in the wake of the submerged mandible is not high enough to wet the bird's neck or belly, and the height of this wave may be influenced by the series of ridges on the mandible. Although the wingbeat is restricted to an arc of about 45°, the skimmer compensates by its relatively low wing-loading and by an aerodynamic surface effect that increases lift and reduces drag when birds fly within a few centimetres of the substrate. Friction between the bill and the water is not a significant factor because hydrodynamic drag is almost nil for the highly streamlined mandibles. In fact, skimming is often accomplished while gliding or with intermittent wingbeats. Flight speed during skimming is typically 16-32 km/h, but in strong headwinds it may be much slower.

Crepuscular and nocturnal feeding are regularly practised by all species of skimmer. Benefits of nocturnal foraging might be that some species of fish come closer to the surface and strong daytime winds often diminish. Tactile feeding at night provides ecological segregation from diurnal fish-eaters, and even during the day it enables skimmers to forage in opaque, silt-laden water where fish are less available to visual predators.

The average skimming time required to catch a fish is extremely variable depending on the size of the prey, its density and the depth at which it is situated. Measured rates vary from

Black Skimmers typically start to assemble at a colony a week or so before nesting begins in earnest. During this time there is great deal of activity, as groups and pairs indulge in aerial displays and chases with much calling, as partnership bonds are established, although some birds may already be paired when they arrive at the colony. Colonies tend to be situated on coastal islands and isolated beaches. If breeding is successful at a given site one season, the same site is normally occupied and used again the following year.

[*Rynchops niger niger*, Long Island, New York. Photo: Tom Vezo]

one catch per minute to one per seven minutes. An exceptional rate occurred at a small pond near the coast of Texas, at which several Black Skimmers fished actively all night, skimming in the central portion of the pond. Just before sunrise myriads of small fish congregated at the surface and formed a dense border that was clearly visible around the pond. Birds then skimmed only through this concentration, where they averaged one fish caught per three seconds of skimming time. It is not uncommon for skimmers in any situation to direct their skimming towards surface disturbances made by schools of fish.

How did skimming behaviour and its associated structural modifications evolve? If we assume that extant gulls and terns are less modified than skimmers from the common ancestor of all three, then we might ask whether extant, unspecialized larids are capable of skimming. In fact, Laughing Gulls (*Larus atricilla*) have been observed repeatedly skimming stretches of up to two metres at a time with the distal third of the lower mandible immersed in turbid water. The birds always flew directly into the wind while skimming, and fish-catching was not observed. Terns also skim on occasion, perhaps to drink, but observations of Royal Terns (*Thalasseus maximus*) revealed that birds catching small crabs by plunging usually skimmed briefly after a catch, presumably to clean the bill; the birds actually caught fish, perhaps inadvertently, during three among hundreds of such observations of skimming.

Probably extreme streamlining of the bill evolved rapidly under strong selection after skimming became an important feeding method of the ancestral skimmer. Other refinements in bill structure, proportions of the skeleto-muscular system, wings and eyes could then evolve gradually and individually because each would improve the efficiency of skimming, and hence the bird's fitness, in its own way. Other ancestral feeding methods would eventually become difficult or impossible as the specialization for skimming approached its present level.

Breeding

Most breeding in South America, Africa and southern Asia takes place between April and November, during what tends to be the period of low water in major rivers, but the dates vary locally and from year to year, depending on the termination of the rainy season in the headwaters. In North America, breeding is more strictly seasonal, usually from April to July, although this can be extended to early September in the event of renesting.

Although the three species are colonial nesters, colonies sometimes consist of only a few pairs, and even single pairs may breed successfully. Skimmers either join terns, and sometimes gulls, plovers and other species, or they form pure colonies. Colonies usually number less than 200 pairs, and most actually support less than 100, although exceptionally several thousand pairs may congregate, without counting the associated species.

Preferred colony sites for North American skimmers are the more isolated tracts of suitable habitat, particularly coastal islands and beaches, but birds also nest with terns on mats of dead vegetation deposited in salt-marshes by winter tides. When selecting a breeding site in any given year, an individual bird may simply return to its previous breeding location, or it may be at-

A pair of Black Skimmers vigorously defend the nest-site as an intruder appears, in this case a Common Tern (Sterna hirundo). *Skimmers frequently form nesting colonies with other species, in particular with Common Terns, which are more aggressive and provide the skimmers with some extra protection from predation by gulls. However, there are limits to the behaviour one can tolerate from one's neighbours!*

[*Rynchops niger niger*, Cedar Beach, New York. Photo: A. & E. Morris/ Birds As Art]

Monogamous in their breeding habits, Black Skimmers indulge in a variety of displays in order to help establish and maintain the pair-bond, the most usual being courtship feeding, when the male presents the female with the gift of a fish. Very often such a presentation is made just prior to copulation, which takes place at the nest-site; the female typically holds the fish in her bill while the male mounts her, and she tends to swallow it only once copulation is over.

[*Rynchops niger*. Photo: Mike Wilkes/Aquila]

tracted to other birds nesting in a new location, rather than favouring specific physical features of the environment. Skimmers are not bound by tradition when conditions are unfavourable, and they will renest in a different place in the same year if the first attempt is unsuccessful. A study in New Jersey, USA, showed that Black Skimmers are more likely to choose a new colony site in the succeeding year if the previous year's colony was destroyed by predators than if it was flooded, probably because predators are likely to return to the site year after year whereas floods are unpredictable. Such flexibility is important to the birds of South America, Africa and southern Asia, where colonies on riverine sandbars or beaches are subject to flooding when local rains cause sudden fluctuations in water level.

Black Skimmers accumulate at the colony site for about a week before most breeding activities begin. Pairs or groups of birds engage in aerial chases during pair formation, but some birds are already paired, and courtship feeding may occur within packed groups, which gradually give way to more evenly spaced pairs. Although skimmers usually breed in the company of terns, they tend to cluster near the middle of the colony.

The skimmer's nest is formed by the bird kicking sand backwards while it rests on its belly and turns slowly in concentric circles. Later, the chicks use a similar technique to bury themselves partially in the sand for protection. The finished nest cup is about 20-30 cm in diameter and 2-4 cm deep. Several such scrapes are made in the territory but only one is chosen for laying. Even a bare cup serves to shield the eggs and young from extremes of temperature and to make them less conspicuous; it also prevents the eggs from being scattered by the wind. Copulation occurs at the nest-site after a male offers the female a fish, which she often holds during mounting, and eats following copulation.

The size of the defended area around the nest varies inversely with the size of the colony, and according to the stage of breeding activities. Territories are smallest during the incubation period, when activity is at a minimum, but larger before and during egg-laying, when the pair must repel intruders attempting to find nest-sites, or to steal fish brought by the male for courtship feeding or held by a female during copulation. Males aggressively defend their mates from other males attempting to interrupt or steal copulations. Defence and aggression increase again once the chicks begin to wander away from the nest cup; neighbouring birds usually stab at such chicks, sometimes killing them. At this time, females are especially aggressive toward intruders of both sexes. A parent may attempt to recover its wandering chick by carrying it in the bill, but more often it tries to drive away the menacing neighbour. Skimmers have a variety of aggressive displays, one of the commonest being the "Aggressive Upright", in which the neck is extended vertically and the bill held horizontally or raised about 45° at highest intensity; the bill may be opened or closed and the wings are held slightly away from the body. This display usually precedes an attack on the ground or in flight. The Black Skimmer's bark also indicates aggression, when it becomes shorter and sharper if uttered from the ground, or longer and harsher if given in flight. Unlike terns and gulls, skimmers often perform a distraction display consisting of spreading or dragging the wings, lowering the head and body, and stumbling movements, when gulls, other skimmers or large mammals, including humans, approach their young.

Skimmers' eggs are pale grey, sandy, buff or olive with bold brown and purplish blotches and lines, ranging in size from 4·5 x 3·3 cm in the Black Skimmer to 3·9 x 2·8 cm in the African Skimmer. Clutch size usually numbers 2-6 eggs, and typically averages either 3-4 or 2-3 eggs; a gradient from 4 to 2-3 eggs may occur from north-west India to Burma. Second and third clutches, following nest failure, are generally smaller than the first.

In the Black Skimmer, the period of egg-laying lasts 4-8 days, whereas that of incubation is 21-26 days. Both sexes incubate, and alternation of incubation becomes critical, and more frequent, when ambient temperatures exceed the incubation temperature of 35·6°C, requiring frequent cooling, not only of the eggs but also of the parents. Under these conditions a bird relieved from incubation flies directly over water, patters its feet, and ploughs the surface with its breast feathers, which serves not only to cool the bird but also to wet and cool the eggs upon its return to the nest. Such exchanges are frequent during the heat of the day, when shade temperatures at ground level may exceed 50°C, but in more moderate temperatures changes at the nest mainly coincide with foraging activity.

Because incubation begins with the first egg, the chicks hatch asynchronously over about four days. Studies differ as to whether

The Black Skimmer may prepare several nests by kicking sand backwards while it pivots round in circles on its belly, but only one will be used for laying. The cup-shaped depression thus formed is usually 2-4 cm deep and will hold 2-6 eggs, pale in ground colour with heavy brown and purplish blotches. The sexes take turns in incubating, which may last up to 26 days. When temperatures soar, the bird leaving the nest often flies to water to wet both the feet and the breast feathers. Once it has refreshed itself, it may return to the nest where the eggs are then wetted and cooled to help maintain them at a constant incubation temperature.

[*Rynchops niger*. Photo: Steven C. Kaufman/Bruce Coleman]

the first chick hatched dominates the others and survives at their expense, or whether most or all chicks survive. Such differences may depend on the abundance of food in a given year or locality. While feeding young, adults bring single small fish to the colony from foraging areas that may be 2-8 km away. Black Skimmers less than six days old were fed fish less than 5 cm long at a rate of 3-4 fish per 10-20 minute period, followed by several hours of inactivity. Undigested material is regurgitated in the form of a pellet. Sometimes chicks peck at fresh pellets, giving rise to the statement that they are fed by regurgitation, but in fact they take fish directly from the parent's bill, or if dropped, from the ground. A fish too large to be swallowed by a chick may be softened by parental mandibulation.

Apart from sibling rivalry for food, the chick's life is precarious in several ways, as it depends on both parents for shelter from heat and rain, protection from neighbouring skimmers and terns, and protection from predators. The chick's behaviour also contributes to its survival in aspects such as the recognition of its own parents, competition for fish held in the adult's bill, crouching in the scrape or digging into the sand for camouflage, seeking shade in vegetation to avoid heat stress, and running rapidly when necessary. After fledging, which takes about four weeks in the Black Skimmer, young birds soon accompany their parents on foraging excursions, but they continue to be fed for at least two weeks more. Adults and young congregate in open areas prior to final departure from the colony.

Hatching success is highly variable, mainly because of flooding or predation, either of which may destroy a colony. Renesting may occur once or twice in a season, but in the absence of catastrophe nesting occurs only once, and hatching success may be as high as 85%. Fledging success is typically lower, ranging from 0 to 1·4, or occasionally 2, young per pair, and one factor is that chicks 7-15 days old that are no longer brooded rarely survive periods of heavy rain lasting two or three days. Some of the more important predators of eggs and young include small to medium-sized carnivores, crows, gulls, raptors, snakes and large lizards. Skimmers benefit from intense mobbing of such predators by terns, and sometimes they participate in this behaviour, particularly when terns are less numerous. A hazard beyond the control of African Skimmers is the trampling of eggs and young by hippos, elephants and cattle, which may all use sandbars as walkways.

Movements

The daily cycle of movements is mainly between feeding grounds and resting areas or the breeding colony. Some movements are also related to tidal cycles, when most resting occurs during high tide. In Florida, Black Skimmers may fly 70 km inland each night to feed at lakes.

Post-breeding dispersal of North American Black Skimmers involves mostly immature birds, but both immatures and adults have been recorded far inland in the USA and Mexico. Some, but not all, of these were presumably storm-blown, and records from Newfoundland have been linked to hurricanes, which often move north-eastwards up the Atlantic coast.

Both young and adult birds migrate and flock together. Populations that breed in north-eastern North America shift south to Florida and the Gulf coast, while many of the more southern breeders winter on both coasts of Central America, south to Panama. On the great rivers of South America, Africa and southern Asia, birds migrate between their breeding grounds up-river and the non-breeding grounds near the river's mouth or on the coast; the distances involved may amount to hundreds, or even thousands, of kilometres. In Africa, many birds leave the main rivers to spend the non-breeding season at Lake Chad, the Rift Valley lakes or other inland sites.

An intriguing question in South America is the origin of the Black Skimmer populations of the race *cinerascens*, which winter along the Pacific coast from Ecuador to southern Chile. Except for a breeding population in the Gulf of Guayaquil, this subspecies breeds mainly east of the Andes on the Orinoco, Amazon and Paraná Rivers and their major tributaries, as far west as eastern Colombia and eastern Peru, almost to the Andes. Do some of these birds move westwards over the Andes to reach the coast? If so, they probably represent the populations breeding in the western Amazon Basin, as their non-breeding period coincides with the appearance of birds on the west coast; more northerly birds apparently breed later and probably migrate to the north coast of South America and Trinidad. Non-breeding birds have been recorded on the Bolivian shores of Lake Titicaca, at an altitude of 3800 m, indicating that skimmers are certainly capable of traversing high mountainous zones.

Relationship with Man

Although skimmers are unique and distinctive in appearance and behaviour, they do not appear to have played an important role in folklore, ritual or pictorial representation of the indigenous peoples within their range. Extensive use of plumes and whole birds, such as terns, for millinery and other forms of decoration in the nineteenth and early twentieth centuries in North America and Europe brought some terns and herons nearly to extinction (see Volume 1, page 396), but skimmers were not in great demand for this trade.

The eggs of all species of skimmers are used regularly for food by native and immigrant peoples, and they are especially valued for their large size. In North America, eggs are still taken for this purpose despite their protection under Federal and State Laws. In the past, egg-collectors took large series of skimmer eggs in order to represent the striking variation in markings and background colours.

Status and Conservation

Due to the fact that skimmers tend to have a rather scattered distribution, often at low densities, their numbers are often difficult to estimate with any real degree of certainty. A few incomplete censuses of the Black Skimmer, mostly from the 1950's-1970's indicated about 68,000 breeding birds on the Atlantic and Gulf coasts of the USA, with most of these birds in Louisiana and Texas. The largest recorded wintering flocks were 10,000 birds in North Carolina in 1935 and again in 1964. There are few data from the Neotropics: on the rivers of South America they are usually sighted in small flocks, and the few colonies for

which numbers have been reported are also small, in the range of 5-50 pairs, although admittedly such flocks and colonies may go unrecorded along hundreds or thousands of kilometres of river. The entire populations of African and Indian Skimmers are each estimated at something in the region of 10,000 birds, but the latter species is now considered globally threatened.

Even for the best-censused taxon, the North American Black Skimmer, it is difficult to say whether populations have remained stable, increased or declined during the twentieth century. Censuses performed in different years are often at different localities, or taken in different ways, and are thus not comparable. Apparent differences in local populations or numbers of colonies occupied between years may simply reflect a local shift in colony sites. During a given decade, skimmer populations may increase in one area and decrease in another, with no net change. Although populations of North American skimmers appear to be stable, it is doubtful that their numbers have recovered from the intense egging and hunting for food, including commercial exploitation, that occurred in the nineteenth century.

How vulnerable are skimmer populations to human predation, disturbance and environmental manipulation? All three species are adapted to endure natural disasters and heavy predation at colonies by a readiness to renest and change the colony site. The Black Skimmer uses structures such as dredge deposition islands, levees, causeways and gravel roofs for breeding. In marsh habitats on the north Gulf coast, dredge deposition from recent oil exploration has provided new colony sites for skimmers, and, indeed, a significant proportion of all nesting in the USA now takes place on dredge islands comprised largely of sand and shell. Nevertheless, plant succession makes much of the dredge habitat unsuitable within a few years, and breeding on gravel roofs is almost entirely unsuccessful. To a large extent, use of artificial habitats by skimmers results from their displacement from natural beach and barrier islands because of recreational use, commercial development, and predation by dogs, cats, rats and humans.

Black Skimmers are adaptable in their use of feeding sites, accepting man-made ponds, ditches and shipping channels if fish are abundant. However, they are specialized in their basic needs, namely open, calm water with high concentrations of fish either in shallows or near the surface of deeper water. Thus, they are vulnerable to any major threat to fish populations, such as coastal oil spills and chemical pollution of estuaries from various industries and agricultural run-off. Another danger is in the form of toxic water pollutants deposited in fish tissues, including organochlorines, such as DDE and PCB's, used for insect control related to public health or agriculture, and heavy metals and selenium from industry. Black Skimmers are known to accumulate organochlorines in their eggs and heavy metals in their feathers, but the extent to which current levels of such toxins affect reproduction or adult viability is not well known.

We lack information about the prey species of South American skimmers at their different localities, and it is therefore difficult to predict the long-term effects of various land use and fishing practices on skimmer populations. The birds breed along nutrient poor clear-water and black-water rivers, as well as nutrient rich white-water rivers. Fish faunas in the latter are sustained by phytoplankton and zooplankton, while those in clear- and dark-water rivers depend heavily on fruits, seeds and insects that fall from the flooded forest at periods of high water. Cutting of riverine forest would thus seriously deplete the fish stocks in nutrient poor rivers. Riverine breeding habitat in the Amazon, Orinoco, Paraná and lesser drainage basins is admittedly vastly extensive, but rivers are also the focus of human settlement and agriculture, which proceed at a particularly rapid pace with the construction of new roads. A hope for the future is that large stretches of river and adjacent forest will be preserved to protect local fishing industries, a development that would certainly benefit the skimmers. Human predation on skimmer eggs is already a serious threat in the Neotropics, and increased use of beach habitat will displace colonies there, as it has done in North America.

Non-breeding birds migrate in part to estuaries, which are also focal points for large human populations; other birds spread along the coasts where human impact on their environment has been little studied outside North America.

The Indian Skimmer is judged to be at risk, and is currently classified as Vulnerable. The entire population may not number more than 10,000 birds. While little is known of former population sizes to help estimate the amplitude of the apparent decline, it is obvious that, as a species of broad rivers and estuaries, its habitat is coming under increasing pressure. Huge human populations continue to grow, while at the same time dam and irrigation projects, and the ever more frequent use of sandbars for agriculture, are also contributing to reduce the amount of suitable habitat available to the species.

[*Rynchops albicollis*, India. Photo: Goran Ekström/ Windrush]

The future of the African Skimmer will also depend on the preservation of sufficient riverine breeding habitat, free from excessive human disturbance. Construction of dams and river bar agriculture have removed extensive areas of breeding habitat. In addition, conditions also need to remain favourable on the large lakes where many birds spend the non-breeding season. Some of the Rift Valley lakes are particularly vulnerable to environmental perturbation by pollution because of their extremely low rates of water turn-over. Their remarkably diverse faunas of cichlid fishes are subject to reduction or annihilation by introduced predatory fish, as has already happened in Lake Victoria with the Nile perch (*Lates niloticus*), introduced in the 1960's.

The Indian Skimmer is currently classified as Vulnerable. It is a bird of large rivers and estuaries, and has to contend with massive human populations along rivers, especially the Ganges, as well as extensive pollution in some areas, large hydro-electric and irrigation projects, and cultivation of sandbars during the season of low water. Little is known about its former and present populations, but comparison of early anecdotal accounts and recent censuses suggests a marked decline throughout its range in recent years, a pattern mirrored by a large number of Asian waterbird species. There is no doubt that the plight of this species requires careful monitoring in the years to come.

Despite the skimmers' resilience to moderate levels of human disturbance, we must be concerned about their ability to withstand interference from increasing human populations and modification of their habitat. Major breeding colonies are protected from human access to some extent in the USA, but recommendations for management of dredge islands to maintain suitable habitat have been largely ignored. Preservation of the natural environment along extensive portions of the major tropical rivers of the world may prove to be necessary for the long-term survival of Asian, African, and South American skimmers.

Genus *RYNCHOPS* Linnaeus, 1758

1. Black Skimmer

Rynchops niger

French: Bec-en-ciseaux noir **Spanish**: Rayador Americano
German: Amerikanischer Scherenschnabel
Other common names: American Skimmer

Taxonomy. *Rynchops nigra* Linnaeus, 1758, America = coast of South Carolina.
Forms superspecies with *R. flavirostris* and *R. albicollis*; some authorities have suggested that all three might be conspecific, but good evidence apparently lacking. Species name changed from *nigra* to *niger*, when all genera ending in *-ops* were ruled as being of masculine gender. Races *cinerascens* and *intercedens* formerly considered to constitute two further species, on account of white, as opposed to dusky, on wing linings and tail, and amount of white edging on secondaries; however, variability of these characters is more consistent with subspecific differentiation. Dubious race *intermedia* (W South America) normally included within *cinerascens*; proposed race *melanura* is synonymous with *cinerascens*. Three subspecies normally recognized.
Subspecies and Distribution.
R. n. niger Linnaeus, 1758 - coasts of USA (S California; Massachusetts to Texas) and Mexico (Sonora to Nayarit; Tamaulipas to Yucatán Peninsula); winters from California and North Carolina S to both coasts of Panama.
R. n. cinerascens Spix, 1825 - coasts of Colombia to mouth of R Amazon and W Ecuador (Gulf of Guayaquil), and large river systems (especially Orinoco and Amazon) S to Bolivia and NW Argentina; winters on coasts, from Ecuador to S Chile, and from Panama to Trinidad and NC Brazil.
R. n. intercedens Saunders, 1895 - large rivers of E Brazil (W to Maranhão and E Mato Grosso), E Paraguay, Uruguay and NE Argentina (S to Bahía Blanca); winters mainly on coast.
Descriptive notes. 41-46 cm; male 308-374 g, culmen 64-74 mm; female 232-295 g, culmen 52-65 mm; wingspan 107-127 cm. Unmistakable within range. Differs from *R. flavirostris* in larger size and

dark bill tip; from *R. albicollis* by black hindneck in breeding plumage, and dark bill tip. Wing lining white in nominate race, with secondaries and inner primaries broadly edged white, and tail white with dark central streak. Non-breeding adult has white nuchal collar and somewhat browner upperparts. Female similar to male in plumage, but smaller. Immature similar to non-breeding adult, but generally browner above, with some streaking, scaling and mottling, and duller bill. Race *cinerascens* has longer wings and bill than nominate *niger*, wing lining grey (whiter in immatures), narrow white edging on secondaries, and tail sooty; race *intercedens* resembles *cinerascens* in size, with wing lining white or greyish, white on secondaries variable, and tail grey (intermediate between *cinerascens* and *niger*).
Habitat. Mainland coast or barrier islands on sandy beaches, sandbars, shell banks, dredge islands and mudflats; tidal pools, inlets and creeks; salt-marsh wrack and creeks; ponds, lagoons and estuaries. In South America, frequents larger rivers at low water, coastal beaches and lagoons, islands and estuaries; breeds on sandbars and beaches of large rivers during season of low water. Recorded up to 3800 m on Bolivian shore of L Titicaca.
Food and Feeding. Mainly fish, e.g. in USA, silversides (*Menidia*), killifish (*Fundulus*), minnows (*Cyprinodon*), mullet (*Mugil*), anchovy (*Anchoa*), menhaden (*Brevoortia*), mollies (*Poecilia*); also some crustaceans, especially shrimps (*Palaeomonetes*, *Penaeus*). Food caught exclusively by skimming the water in flight with mouth open and lower mandible submerged; prey items touched by mandible are grasped while head doubles back under body; prey swallowed in flight or after landing.
Breeding. Birds of nominate race arrive at breeding grounds from mid-Mar to early May, laying from late May, or as late as Sept when renesting; season mainly May-Oct in upper basin of R Amazon; Oct-Mar in N Brazil, N Venezuela, N Colombia; season of race *intercedens* not well documented, but Sept-Nov on Rio Uruguay (Entre Ríos, Argentina). Colonial, with few to over 1000 pairs, but sometimes single; usually nests in company of terns, in Brazil commonly alongside Large-billed Terns (*Phaetusa simplex*). Nests on sand or shell beach; in USA, also on island of dredged material, sometimes on marsh wrack or gravel roof; nest is simple depression in substrate. Clutch usually 3-4 (mean 3·6) on

Atlantic coast, 2-3 on Gulf coast and in Colombia and Brazil; incubation 21-26 days, starting with first egg; semi-precocial chick has greyish buff down, irregularly and sparsely spotted black; leaves nest after about a week; brooded and fed by both parents; fledging 28-30 days. Fledging success in USA 0-2·77 young/pair, but often less than 1. Natural predators at colonies include foxes (*Vulpes*, *Urocyon*), weasels (*Mustela*), and racoon (*Procyon*). Age at first breeding not well established, but probably 1-3 years; maximum lifespan in wild at least 20 years.

Movements. Migratory. Northernmost breeding zones vacated Nov-Mar, birds wintering scantily S from North Carolina, and in greater number S from South Carolina to Florida, and down Gulf coast and both coasts of Mexico to Panama; sometimes carried far afield by storms, e.g. to Newfoundland, inland USA and Mexico, West Indies and Venezuela. Non-breeding *cinerascens* arrive in Chile in Oct, leaving in May; present in Trinidad May-Nov. Non-breeding *intercedens* on coast and estuaries mainly Dec-May, but poorly documented.

Status and Conservation. Not globally threatened. Population estimates unavailable for most of extensive range; in late 1970's, estimated total population of USA was c. 68,000 birds, with c. 70% in Louisiana and Texas. In USA, preferred breeding site of sandy beaches conflicts with increasing human use for recreation and commercial development; most colonies already displaced to dredge islands; Florida breeding sites reduced in number because of boating and other human disturbance. Chemical pollution also of concern; organochlorines (DDE, PCB) in eggs and heavy metals and selenium in body tissues and eggs potentially detrimental to reproduction; sample eggs from nests where none of remainder hatched showed higher concentrations of DDE (mean 5·9 ppm) than those from nests where all others hatched (mean 1·9 ppm). Oiling of plumage is not a common problem. Predators associated with humans, notably dogs, cats and rats, damage some colonies. Numbers in Mexico and wintering along Pacific coast of South America apparently much reduced since mid-19th century; pre-migration flocks of 1000-1500 birds near Valparaiso, C Chile, in 1960's. Reported to be common during early to middle 20th century at Gulf of Guayaquil in Ecuador, along lower R Magdalena in Colombia, and at several localities in Venezuela. Common breeder at Manu National Park, Peru, in 1980's-1990's.

2. African Skimmer

Rynchops flavirostris

French: Bec-en-ciseaux d'Afrique **Spanish**: Rayador Africano
German: Afrikanischer Scherenschnabel
Other common names: Scissorbill

Taxonomy. *Rhynchops* [sic] *flavirostris* Vieillot, 1816, "Australasie"; error = Senegal.
Forms superspecies with *R. niger* and *R. albicollis*; some authorities have suggested that all three might be conspecific, but good evidence apparently lacking. Monotypic.

Distribution. Major rivers and lakes of Africa S of Sahara, from Senegal E to Sudan and SW Ethiopia, and S to extreme N Namibia (R Kunene), N Botswana, basin of R Zambezi and S Mozambique; may have bred on L Nasser, Egypt, in 1987. Non-breeding visitor NW to R Gambia and Egyptian stretches of R Nile.

Descriptive notes. 36-42 cm; 111-204 g; wingspan c. 106 cm; culmen of male 61-70 mm, of female 51-62 mm. Unmistakable within range. Smaller than congeners; differs from *niger* by pale whitish yellow tip to bill; from *albicollis* by black hindneck in breeding plumage. Non-breeding adult has white nuchal collar and somewhat browner upperparts. Female similar to male. Immature similar to non-breeding adult, but generally browner above, with buff fringing and mottling, and paler bill.

Habitat. Rivers at low water, coastal lagoons, salt-pans, open marshes, lakes; less common along coast. Rests and breeds on sandbars and beaches.

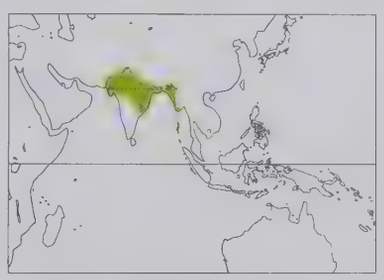
Food and Feeding. Fish, e.g. cichlids. Crepuscular and nocturnal, as well as diurnal. Food caught exclusively by skimming the water in flight with mouth open and lower mandible submerged; prey items touched by mandible are grasped while head doubles back under body; prey swallowed in flight or after landing.

Breeding. Laying generally Mar-Jun in W & E Africa, mainly Jul-Nov S of equator; season varies locally depending on local dry season and period of low water in river. Colonial, often with terns, plovers, pratincoles and other species; birds chase one another noisily day and night on arrival at colony. Nests on sandy beaches and sandbars in rivers and islands in lakes; nest is unlined scrape in sand. Clutch 2-3 (mean 2·6), rarely 4, laid over several days; incubation c. 21 days, by both sexes, but mainly by female; chick has buffy white down, with irregular peppering of small black dots; tended and fed fish by both parents; stays in nest scrape for 2 days; fledging c. 4 weeks. Rising river water may destroy colony; eggs may be trampled by hippopotami and elephants; predators include raptors and other birds, mammals, lizards and snakes; parents will mob some species even away from nest, others only when near nest.

Movements. Migrates up and down larger rivers, and to and from inland lakes. Uncommon on coast, but outside breeding season may congregate in estuaries, e.g. well over 200 birds together off Bonthe, Sierra Leone, in Jan.

Status and Conservation. Not globally threatened. Total population estimated at less than 10,000 birds; largest colony supports only 50 pairs. Census on 1550 km of upper and middle R Zambezi yielded 1428 birds; largest recorded flocks of non-breeders include 1000 birds in Kenya and 1500 in Tanzania. South African populations decreasing; species no longer breeds in Natal. Dams flood habitats upstream and alter flow downstream producing unsuitable breeding conditions; DDT spraying for malaria and against tsetse fly and agricultural pests is dangerous for fish-eaters. Egg-collecting routinely practised, and this is facilitated by fact that incubating adults tend to be conspicuous; in addition, disturbance of colony by humans and cattle during hottest season is often fatal to eggs and chicks. Pollution, overfishing and decimation of native fish faunas by introduced predatory fish is a potential problem in many lakes.

(1979), Turner & Gerhart (1971), Urban *et al.* (1986), Verschuren (1978), Williams, A.J. (1986).



3. Indian Skimmer

Rynchops albicollis

French: Bec-en-ciseaux à collier **German**: Indischer Scherenschnabel **Spanish**: Rayador Indio
Other common names: Scissorbill

Taxonomy. *Rhynchops* [sic] *albicollis* Swainson, 1838, India.
Forms superspecies with *R. niger* and *R. flavirostris*; some authorities have suggested that all three might be conspecific, but good evidence apparently lacking. Monotypic.

Distribution. E Pakistan (R Indus) through N & EC India (E to Assam) to Bangladesh and W Myanmar (R Irrawaddy); also Cambodia (R Mekong). Current distribution uncertain: might also breed in Nepal and S Laos; possibly only winter visitor to Bangladesh.

Descriptive notes. 38-43 cm; wingspan 102-114 cm; culmen 58-75 mm. Unmistakable within range. Differs from *R. niger* and *R. flavirostris* by having white collar in adult breeding plumage; tail white with inconspicuous dark centre stripe. Non-breeding adult has somewhat duller, browner upperparts. Female similar to male, but somewhat smaller. Immature similar to non-breeding adult, but generally browner above, with buff scaling, and duller bill.

Habitat. Largely restricted to major rivers, particularly along calm stretches with sandbars; rare or vagrant to estuaries, inshore coastal waters and freshwater tanks.

Food and Feeding. Fish and shrimps. Crepuscular and nocturnal, as well as diurnal, sometimes foraging on moonlit nights. Food caught exclusively by skimming the water in flight with mouth open and lower mandible submerged; prey items touched by mandible are grasped while head doubles back under body; prey swallowed in flight or after landing.

Breeding. Generally mid-Feb to Jun, with local variations. Colonial, often with terns and pratincoles. Nests on sandbanks of larger rivers during season of low water; nest is an unlined scrape in sand. Clutch usually 4 eggs in NW India, 2-3 eggs further E; incubation c. 21 days, by both sexes but mainly by female; chick has greyish or sand-coloured down with scattered dark brown spots. Predators on eggs and young include Pallas's Fish-eagle (*Haliaeetus leucoryphus*), crows, kites and jackals.

Movements. Moves upriver during season of low water, and down during period of floods. Occasionally visits lakes. Vagrant to SE China, Thailand and Vietnam.

Status and Conservation. VULNERABLE. Total population estimated at c. 10,000 birds, but status very poorly documented throughout most of range. In India, still fairly common locally but only 18 birds recorded in mid-winter counts, 1991. In Pakistan, has apparently declined over last 50-60 years; in latter part of 19th century was tolerably common all along R Indus, but by mid-1960's no birds at all seen except during monsoon season; main cause of decline is probably habitat loss, as result of damming of major rivers, which reduces risk of flooding, and encourages human populations to move in and cultivate river islands and sandbars. In Nepal, species is uncommon and irregular winter visitor near Indian border; may have bred. In Bangladesh, no recent breeding records; local winter visitor to coast and major rivers, where c. 3000 birds counted in 1988/89, and 602 birds in 1991. No recent records from Bhutan. Formerly common locally in Myanmar, but now rare. Rare or merely vagrant to other parts of SE Asia, but may breed in Cambodia. Human disturbance and habitat modification are probably the greatest threats throughout range.

Class AVES

Order CHARADRIIFORMES

Suborder ALCAE

Family ALCIDAE (AUKS)

- Small to medium-sized marine, wing-propelled diving birds with stocky body, short wings and tail, mainly black or dark grey above and white below, and legs placed far back for swimming.
- 12-43 cm.

- Circumpolar.
- Exclusively marine, neritic and pelagic.
- 11 genera, 22 species, 45 taxa.
- 1 species threatened; 1 species extinct since 1600.

Systematics

The fossil record of birds (Aves) *per se* is poor, significantly less than its mammalian counterpart. Current paleontology of the Alcidae, or auk family, tells us little about the first appearance and evolution of this major taxon. However, with the information that does exist, it appears that the principal radiation of modern genera of Alcidae took place by the late Miocene (6 million years ago) or Pliocene (5-3 million years ago), regardless of how long the family may have been around prior to these times. This broad diversification by the late Miocene does, however, indicate that the auk family was of considerable age by that time and doubtless its roots extend back 40-30 million years earlier or more.

Geological history suggests that the northern Pacific Ocean was the centre of origin for most or all of the modern Alcidae, based largely upon differential stability of the land masses and ocean basins at the time: at the beginning of the Tertiary, some 60 million years ago, the Pacific Ocean was similar in size and shape to its current state, whereas the Atlantic was still a young ocean, very unlike its present form. The genus *Hydrotherikornis* is the earliest alcid group known, from the late Eocene, found in the eastern Pacific. Little is known for the next 40-50 million years until the late Miocene and early Pliocene (6-5 million years ago) when the next Pacific alcids, belonging close to the *Fratercula* puffins, were recorded in deposits from California and Baja California. Pacific species of the genera *Uria* (murres) and *Cepphus* (guillemots) have been documented in the late Miocene, whereas they are unknown in the Atlantic until much later, the Pleistocene (less than 3 million years ago), suggesting a Pacific origin for both genera.

The fossil record for the Alcidae in the Atlantic is richer than that for the Pacific. However, the earliest Atlantic auk is *Miocepphus mcclungi* from the middle Miocene (about 17-15 million years ago), found in Maryland and North Carolina. This, and numerous subsequent fossil finds, indicate a much more recent appearance of alcids in the Atlantic than the Pacific. It seems that the first ones arrived in the Atlantic after the early Eocene, probably much later. The recent fossil record shows only a small number of auks in the middle Miocene in the western mid-Atlantic, with a subsequent rapid and diverse radiation of the family there by the early Pliocene, including *Alca*, *Australca* and *Pinguinus*, and perhaps *Alle* and some undescribed genera. Although *Fratercula* (puffins) is considered to be of Pacific origin, there were two Atlantic species in the early Pliocene, with dispersal from the Pacific to the Atlantic in the late Miocene. Most interchange of marine animals between the two oceans is believed to have occurred during this short time interval, with most species moving from the Pacific to the Atlantic. There is little evidence to support an Atlantic to Pacific movement, with the possible exception of *Alca* which may have entered the Pacific in the late Miocene and subsequently perished. Overall, the fossil evidence indicates an evolutionary origin in the North Pacific followed mainly by a spread to the North Atlantic via the Arctic Ocean. The fact that 18 of the 22 living species breed in the Pacific, with two species common to the Pacific and the Atlantic, also supports the view of a Pacific origin. But future studies may prove this summary to be oversimplified as there remains much more to be learnt about the origin and radiation or dispersal of the Alcidae.

During the last 160 years the Alcidae have been linked with the penguins (Spheniscidae), the divers or loons (Gaviidae), the grebes (Podicipedidae), and the diving-petrels (Pelecanoididae). Although now believed to be members of the order Charadriiformes, their relationships to other charadriiform groups remain uncertain. Evidence of close affinities with both the Lari and the Charadrii has given support for a shared shorebird-like common ancestor of alcids and larids. The current consensus is that Alcidae are charadriiform seabirds placed in a separate suborder, Alcae.

The living Alcidae comprise 22 species in 11 genera that separate easily into eight distinct species groups. The first contains a single small species, the Dovekie (*Alle alle*), which is black above and white below and short-billed; it is largely restricted to the Atlantic and is the only exclusively plankton-feeding alcid in that ocean. The second group comprises three large species, the Common (*Uria aalge*) and Thick-billed Murres (*Uria lomvia*) and the Razorbill (*Alca torda*), which are all blackish above and white below and long-billed; the murres occur in both Atlantic and Pacific, while the Razorbill is restricted to the Atlantic. The third holds three medium-sized species, the Black Guillemot (*Cepphus grylle*), the Pigeon Guillemot (*Cepphus columba*) and the Spectacled Guillemot (*Cepphus carbo*), which are mostly all black in summer; the Pigeon and Spectacled Guillemots are found in the Pacific and the Black Guillemot in the Atlantic. The fourth group numbers two small species, the Marbled (*Brachyramphus marmoratus*) and Kittlitz's Murrelets (*Brachyramphus brevirostris*), which are chiefly darkish brown

in summer, scaled or barred; both are restricted to the Pacific. In the fifth group are four small species, Xantus's (*Synthliboramphus hypoleucus*), Craveri's (*Synthliboramphus craveri*), the Ancient (*Synthliboramphus antiquus*) and the Japanese Murrelets (*Synthliboramphus wumizusume*), which are all mainly dark above and white below, short-billed and with precocial young; all are Pacific species. The sixth group contains five small species, Cassin's (*Ptychoramphus aleuticus*), the Parakeet (*Cyclorrhynchus psittacula*), the Crested (*Aethia cristatella*), the Whiskered (*Aethia pygmaea*) and the Least Auklets (*Aethia pusilla*), which are darkish grey above and white to grey below, sometimes scaled or barred, with ornamental plumes and short-billed; all are Pacific species. Alone in the seventh group comes a medium-sized species, the Rhinoceros Auklet (*Cerorhinca moncerata*), greyish black above and grey-barred white below, with ornamental head plumes and a robust bill; this is another Pacific species. Finally, in the eighth group are three medium-sized species, the Atlantic (*Fratercula arctica*), Horned (*Fratercula corniculata*) and Tufted Puffins (*Fratercula cirrhata*), which are all black above with white cheeks, white (Atlantic, Horned) or black (Tufted) below, and with large, laterally compressed triangular bills which are brightly coloured during breeding; the first species occurs essentially in the Atlantic, the other two in the Pacific. The extinct Great Auk (*Pinguinus impennis*), the only recent flightless alcid, was black above and white below, and occupied boreal latitudes across the North Atlantic; it shared close affinities with the Razorbill, so strong that it is sometimes included within the genus *Alca*.

Morphological Aspects

The family Alcidae is made up of a highly specialized and ecologically diverse group of marine, wing-propelled pursuit-diving birds. The present day auks are small to medium-sized birds with small wings and short tails, with plumage that is mainly black or dark grey above and white below. They are rather elongated or torpedo-shaped in overall appearance with an orange size range of 12-43 cm long and 140-1100 g in body mass.

The smallest forms are found in the Pacific, the Least and Whiskered Auklets weighing 85-116 g, and Craveri's and Xantus's Murrelets 128-167 g, while the smallest Atlantic form is the Dovekie at 163 g. Intermediate in size are the *Cepphus* guillemots at 400-450 g and the puffins at 375-550 g, while the largest species are those of the genera *Alca* and *Uria*, which weigh 625-750 g and roughly 800-1100 g respectively. The largest recent member of the family, the extinct Great Auk of the Atlantic, probably weighed 5500-8000 g. The rather slight sexual dimorphism in auks is largely limited to body size differences, females tending to be smaller and lighter than males except in Xantus's Murrelet, in which females are larger.

The family shows a circumpolar distribution in an almost unbroken arc mainly in the cold waters of the Northern Hemisphere from eastern Canada through the North Atlantic and eastern shores of the Arctic Ocean to the Bering Sea and North Pacific. Auks are the ecological counterparts of the Southern Hemisphere's penguins, although they are much smaller in size, with the murres barely reaching the size of the smallest member of Spheniscidae, the Little Penguin (*Eudyptula minor*), at 1000 g. Both groups have undergone structural modifications suited for their marine existence, including greatly reduced wings which they use to swim under water in pursuit of prey. While the penguins lost the ability of aerial flight in order to maximize their underwater swimming efficiency, the alcids retained a wing size capable of allowing them to "fly" in both air and water, with the exception of the Great Auk, the last northern member of a succession of flightless alcids that arose in the North Pacific sometime after the Cretaceous. The remarkable underwater propulsion abilities displayed by these two groups are convergent and both groups have undergone somewhat similar and extensive morphological and ethological radiation. Owing to their reduced, or lost, flying proficiency, both are very susceptible to mammalian land predators and have become restricted for breeding to certain locations, normally predator-free islands or inaccessible, sheer sea cliffs within range of an adequate food supply for rearing young. Sites meeting these requirements are rare, and this has led to the formation of large, often immense, single-species or mixed-species colonies. Pen-

Perched photogenically on a cliff, this mixed bunch of alcids is composed of Crested, Parakeet and Least Auklets. Despite size and plumage differences, they show many morphological features in common. Alcids have rather elongated, sturdy bodies; the tail, legs and neck are all short and the head is relatively large. The legs are set far back on the body, while the feet are webbed and the claws adapted to gripping well on uneven surfaces. The rather stubby, narrow wings seem better adapted for diving than for flying. Some species have ornamental crests and plumes, and several have brightly coloured bills.

guins and auks also share certain other life history characteristics that menace their survival: they are long-lived, reach sexual maturity slowly, and have low reproductive rates with correspondingly slow recovery rates. With their 5000 km wide and hemispheric spatial separation, the auks and penguins are true ecological counterparts.

Although the present day auks are less modified in structure for their marine existence than are the penguins, there are many morphological and behavioural features that characterize the family as a whole and each of its member species. Overall, the alcids have elongated and robust bodies with large heads, short necks, short, narrow and generally pointed wings, and short tails. The shortened wing and reduced surface area improves underwater propulsion immensely, but restricts aerial flight by high wing-loading, making it direct, rapid and energetically expensive with limited manoeuvrability once airborne. Take-off is difficult, especially in the medium-sized to large species such as the puffins and murres.

The legs are short, placed well back on the body, and laterally compressed, though not to the same extent as in the foot-propelled diving grebes and divers (loons). The tarsi are fully scutellated, covered in front by transverse scales. The feet are palmate, the first toe being absent or vestigial, and the other three digits fully webbed with the middle one comparatively elongated. Generally, claws are well developed and are used for grasping onto uneven or vertical rocky and rough surfaces, with the second toe in Atlantic and Tufted Puffins particularly strong for excavating underground burrows. All of these features enhance the swimming, diving and overall movement efficiency of the birds in water, in the air, and on land. Under water, the wings propel the bird forward, whereas the feet are used for steering and braking, as they are in aerial flying. Movement on the ground and posture vary between species groups related to the position of the legs. Murres and the Razorbill walk on their tarsal bones and are most limited and upright, whereas puffins walk on their toes, as do most other alcids, and show intermediate mobility on land. The *Cepphus* guillemots and Dovekies display the highest proficiency for ground movement, along with most of the small auklets and murrelets. The post-acetabular part of the pelvis in *Fratercula*, *Cepphus* and *Aethia* is broad enabling these birds to run and use their feet for digging; in addition, the pectorals in *Cepphus* are attached farther forward than in other alcids, maximizing their locomotory abilities on land and permitting more rapid take-off.

Some species, usually colonial breeders, have ornamental crests or plumes, and brightly coloured bills, mouth linings, legs and feet; breeding plumage can be strikingly attractive. Others may be cryptic, particularly species nesting as solitary or widely scattered pairs, such as the Marbled and Kittlitz's Murrelets. Bill shapes and sizes vary greatly, ranging from short and stubby in the murrelets, auklets and Dovekie to fairly long and pointed in the murres and *Cepphus* guillemots, or long and laterally compressed in the Razorbill and the Great Auk. The most impressive are the massive, laterally compressed, broad mandibles of puffins, with brightly coloured ornamental horny plates which are shed during the post-breeding moult. The facial and head ornaments, including the large and colourful bills of puffins, play important roles in pair formation and maintenance, courtship, and agonistic behaviour.

Morphology of the mouth parts varies markedly between species, differences that are associated with food habits and feeding technique. Plankton-feeders have wide bills and a palate densely covered with denticles, as well as a soft, flexible tongue that in six species is combined with a specialized gular throat pouch (sublingual diverticulum) for transporting food to the young over long distances; these species are the five small Pacific auklets and the Dovekie. In contrast, those that are almost exclusively fish-eaters, such as the Razorbill, the Common Murre and the *Brachyramphus* murrelets, have relatively narrow bills and high tongue cornification to press prey against evenly-spaced but less dense palatal denticles. Intermediate between these extremes are the more generalist feeders on fish and plankton, such as the puffins, the Thick-billed Murre and the Rhinoceros Auklet.

The plumage of auks is uniformly thick and heavy with remarkably high insulating qualities. The feathers are short and dense, with numerous feather tracts and down covering the entire body, reaching a density almost twice that found in Laridae. The nostrils are normally covered with feathers from the loral region except in puffins where they are exposed. The uropygial gland at the base of the upper spine is crowned with feathers. The contour feathers have aftershafts, and the apteria are narrow and down-covered, as are the pterylae. There are 11 primaries, the eleventh being reduced and non-functional, and the tenth the longest; the 15-19 secondaries are generally shorter, while the greater secondary and primary coverts are lengthened. The tail is short and normally rounded to wedge-shaped, with 12 rectrices in all genera except *Fratercula*, which has 16, and *Cepphus* with 12-14.

Adults are usually darkish brown to grey and black above and uniformly white to pale white below, both in summer and winter, except for some Pacific species which are more or less darkish brown or grey, sometimes mottled, as in *Aethia* and *Cerorhinca*, or black all over, as in the Tufted Puffin. Other notable exceptions are the *Brachyramphus* murrelets, with their cryptic brown-grey summer plumage and more conventional black-grey above and white below winter plumage, and the *Cepphus* guillemots, with their predominantly black summer and white winter plumages. Sexes are alike in plumage. Juvenile plumage colours are similar to those of winter adults except in the Dovekie and the Razorbill, in which they resemble summer adults; adult plumages are normally attained at 3-15 months, but the horny bill sheaths and plates in several species do not reach adult size until much later, for example at two and four years respectively in *Aethia* and *Fratercula*.

Moult is poorly known. The absence of complete records of plumage condition through the birds' annual cycle, combined with the complexity inherent within a family made up of species with extensive geographical ranges and deferred sexual maturity, make a thorough study of moult pattern and plumage succession extremely difficult. However, all species have one complete and at least one partial moult annually. The post-breeding moult, which occurs in most species soon after breeding is over, is complete, involving all contour and flight-feathers, with the primaries usually shed simultaneously, but gradually in some small auklets. Head and facial ornaments, including crests and plumes, but also ceres, bill plates, eye-rings and fleshy horns, are also lost, accompanied by shrinkage and general fading of other brightly coloured parts like the rictal rosette of puffins, and by colour changes in the legs, in puffins from bright orange to dull yellow, and in *Cepphus* guillemots from brilliant vermilion to pale red, almost pinkish. In spring, the pre-breeding partial moult is slight, usually limited to head, throat area and upper breast, although feather growth can be more extensive in some cases, for example in *Cepphus*. Most species become flightless for a period of up to 45-50 days during the autumn moult, when the flight-feathers are lost and replaced simultaneously; the exceptions are the five small auklets that moult their flight-feathers gradually, which allows them to retain the ability to fly.

In summary, Alcidae as a whole constitute a well defined family with many morphological and anatomical characteristics common to all member species, mostly adaptations for a wing-propelled diving existence. These principal traits and associated functions define alcids as a group and include: efficient wing-propelled underwater swimming and diving; reduced wing size, due to the shortening of the forearm (the antebrachium, the area supported by the radius and ulna), which is always shorter than the carpals and humerus, increasing propulsion efficiency in water; the extended crest of the sternum along its entire length and the enlarged triosseal canal provide enhanced muscle attachments for wings used under water; the thoracic vertebrae are all unfused and thus free, with well developed hypapophyses on the anterior ones for superior attachment of the neck muscles, which combine to facilitate body movement and manoeuvrability under water; and a skeleton which, in order to reduce buoyancy when diving, is virtually non-pneumatic, limited to only the coracoids and scapulae in certain species. Other traits that dis-

This Tufted Puffin in flight reveals a stocky, torpedo-shaped all black body, and rather short, narrow wings, which, though ideal for underwater swimming, make flying rather laboured and take-off from water difficult. It must run, often some considerable distance across the water, before it becomes airborne. In breeding plumage, among the unmistakable features of this puffin are the white face and the yellow straw-like tufts that sprout from behind the eyes and hang down the nape, but most eye-catching of all is the huge, parrot-like salmon red and olive bill.

[*Fratercula cirrhata*, Talan Island, Russia. Photo: Hanne & Jens Eriksen/Aquila]

tinguish the group from most foot-propelled diving waterbirds including divers (loons), grebes and cormorants are: the sternum longer than the synsacrum; the synsacrum broad at the acetabulum; the tarso-metatarsus short and not as laterally compressed; foot area small, relative to body mass; 15 cervical vertebrae; large supraorbital salt glands; the manus or first finger absent; and feather structures including 10 functional primaries, 15-19 secondaries, and 12-16 rectrices. Together, these characteristics also distinguish the Alcidae from other Charadriiformes.

Habitat

Seabirds, defined as those species which spend long periods away from land and obtain all or most of their food from the sea while flying, swimming or diving, occupy all of the world's oceans. This informal group comprises four orders, with all members of Sphenisciformes and Procellariiformes and several of Pelecaniformes and Charadriiformes, including 13 families and in the region of 280 species, all with evolutionary histories that have been principally marine.

Alcidae, one of the most marine of all bird families, is restricted mainly to the colder waters of the Northern Hemisphere, and well reflects the general characteristics of the seabird group. All 22 alcid species have distinct marine evolutionary backgrounds in one or more of the three northern oceans: 16 are restricted to the Pacific and adjacent seas; four to the Arctic and Atlantic; and two occur in both marine regions. Some of the auks are inshore feeders, for instance the *Cepphus* guillemots, while most others feed offshore, foraging over regions of deep water to the edge of the continental shelf, with only a few, notably the Tufted Puffin, extending into the outermost pelagic zone of the open ocean. Regardless of the water region the individual species occupy outside the breeding season, they live continuously at sea and are independent of land for both feeding and resting, usually remaining out of sight of it for much of the year. In general, auks are almost exclusively marine, with most species breeding along sea coasts, on headlands and offshore islands, and wintering mainly in continental shelf waters.

Marine ornithologists have known for some time that the numbers, species composition, and movements of auks in any water region are largely determined by the physical and biological characteristics of the surface waters. The physical features of sea surface temperature, salinity and ice cover in the upper water layers, less than 25 m down, affect the overall pattern of distribution of the birds. Superimposed over these coarse-grained features come the fine-tuned, and often predictable, attributes of water masses, such as special current systems, notably converging and convection currents, areas of upwelling and gyres, the overall interactions and convergences of which lead to high marine productivity. Correlations between the densities of macroplankton and birds are well known and have been instructive when combined with other measures of ocean waters to define distinctive water types and their occurrence worldwide. The northern oceans have been subdivided by oceanographers into four major oceanic zones (restricted to the upper waters), using combined temperature-salinity relationships and distribution patterns of marine invertebrates: the first is the high Arctic, which contains unmixed water of polar origin with surface layers close to freezing (0-3°C) even in August, the warmest month, and salinity usually below 31‰; the second is the low Arctic, which includes mixed high Arctic and boreal water, where the upper water temperatures in August are 4-10°C, with salinities 31-34‰; third the boreal, comprising a broad band with August temperatures of 10-19°C, and salinities of 31-35‰, which overlap with those of the low Arctic zone; and, fourth, the cool subtropical, the waters immediately south of the boreal zone, where August surface temperatures are usually 19-23°C and salinity is over 35‰. The Alcidae breed almost exclusively in boreal, low and high Arctic water zones; only the two southernmost auk species, Craveri's and Xantus's Murrelets, nest on islands in cool subtropical waters of the North Pacific.

The marine environment occupied by the auk family and other seabirds divides easily into two parts: neritic and oceanic waters. The neritic zone encompasses the waters over the continental shelf, normally to the edge, corresponding roughly to the 200 m depth contour. Waters seaward of this, including those of the continental slope, form the oceanic zone. Most auks re-

main within neritic waters throughout the year, varying the selection and use of foraging area and habitat according to the phase of their annual cycle. This restriction of marine habitat use relates directly to marine productivity. Neritic waters generally have higher primary and secondary production culminating in a richer and more predictable food supply than oceanic waters. Vertical mixing of waters over the shelf area from tidal flow and seafloor irregularities, resulting in high nutrient recycling combined with local upwellings close to shore and the input of land-based nutrients through drainage, culminate in unusually high productivity.

Although neritic waters are more productive overall, concentrations of zooplankton and associated foraging fish are not uniformly distributed, causing the birds to disperse in relation to areas of known and predictable high food abundance, or to scatter widely looking for lower-density food patches. During the non-breeding period, many species exploit the full span of neritic shelf waters, using physical characteristics of the surface water layers to identify regions of potentially high prey density. Common and Thick-billed Murres are found offshore to the shelf edge and along sea coasts and in bays where concentrations of their winter fish and invertebrate foods are aggregated, moving in relation to changes in prey abundance. Factors that concentrate their foods such as fronts, converging currents, eddies at headlands and islands, and other fixed oceanographic features are very predictable and therefore attended continuously by large numbers of foraging birds for periods ranging from weeks to months. Other coastal and offshore habitats often contain prey, but at lower densities and for shorter time intervals. Certain species, such as the inshore *Cepphus* guillemots and offshore puffins, exploit these habitat types by dispersing widely to reduce competition with conspecifics and feeding solitarily or in small groups; they are also opportunistic, as short-term food patches are found. Between these two extremes lie a myriad of feeding regimes that have evolved amongst auk species to exploit a limited food supply distributed in a non-random manner over a vast area of ocean. Although significant advances have been made since the early 1970's in understanding the links between the abundance of alcids and their prey and the oceanographic factors responsible, the current insufficiency of knowledge about prey abundance or availability, both temporally and spatially, will limit our ability to identify and define the determinants of alcid foraging niches and their oceanographic correlates. Only through a continued long-term research effort focused on gathering oceanographic and alcid data simultaneously will we be able accurately to define the marine pelagic habitats important to auks.

Alcids also display a marked non-random pattern of distribution in their marine environment during the breeding season. They return to land only to reproduce, often forming immense single-species or mixed-species colonies, like those of the Dovekie or certain *Aethia* auklets. Most species breed in small to large colonies, but some in loose aggregations or scattered pairs, rarely as isolated or solitary pairs. Virtually all breeding sites represent compromises between the oceanographic conditions that provide an adequate and predictable marine food supply and land sites within range of this food source with available nesting sites and few ground predators. Locations meeting these requirements are rare. Even the *Synthliboramphus* murrelets, with precocial young that are taken to sea soon after hatching, are limited to sites where suitable foraging habitats are within easy swimming distance of the colony. Overall, most auk species breed at a considerable distance from their food supply, though obviously not beyond the foraging range that permits them to rear their young successfully.

Together, these severe limiting factors have led to low reproductive rates in most alcid species, normally a single chick each year. Species with two-egg clutches have typically overcome the food factor by either feeding inshore near the colony in shallow waters on benthic prey, as in the case of the *Cepphus* guillemots, or by producing precocial chicks that are taken to sea soon after hatching, as with the *Synthliboramphus* murrelets. In northern regions, ice cover and patterns of break-up also strongly influence the decision of where to breed. In addition to an adequate food supply to feed the young, the surrounding waters must be ice-free early enough in summer to fit in a full breeding season, a period ranging from 60 days in the Thick-billed Murre, for example, to 80-85 days in the Atlantic and Horned Puffins. This means that choice of colony site is crucial, and that many cliffs, islets and islands along sea coasts are likely to lack one or more of the essential requirements for breeding.

Micro-requirements at the breeding site can also be limiting. For species nesting in crevices in rock talus or scree slopes, such as the Dovekie and numerous small auklets, the cavity must not only be accessible and available, but also dry, of the correct size, with certain features of drainage and snow melt that satisfy minimum requirements for incubating an egg and rearing young. Needs of subterranean burrow-nesters like Atlantic and Tufted Puffins are equally demanding, namely a soil type suitable for excavation as well as a vegetative complex that stabilizes and maintains the integrity of the breeding habitat. For surface-breeders such as Thick-billed and Common Murres, the fine-scale features of the bare rocky ledge are of great importance for successful incubation and chick-rearing, and include general characteristics such as height above the sea, steepness of cliff-face, and site-specific details like angle of slope, sides and cover. The same holds for the family's two lowest-density breeders. The Marbled Murrelet searches out moss- and lichen-covered branches of large old-growth coniferous trees that are suitable for using as platforms for nests, and safe from aerial and ground predators; it sometimes nests on open ground. Kittlitz's Murrelet nests alone on the ground in tundra vegetation or on rocky mountain slopes. Both species often breed considerable distances inland from the sea coast. This micro-habitat selection of the actual breeding site is a major determinant of the life-time reproductive performance of individual breeding pairs, probably second in importance only to the general location of the colony or breeding site.

Taken together, all species require suitable land-based habitat for breeding, free from ground predators and in close proximity to an adequate food supply. In Alcidae, the high degree of coloniality, with birds of most species concentrated at a small number of locations, indicates that places to breed possessing all basic ecological requirements for successful reproduction are few. Marine productivity also shapes the dispersion after breeding causing most species to be aggregated in space and time. Such clumped concentrations throughout the annual cycle make most alcids highly vulnerable to human activity and disturbance in marine waters.

General Habits

Alcids are highly social, with most species breeding in colonies, and only a few in loose aggregations or nesting solitarily. Some colonies may be enormous and contain over a million birds, such as those of the Dovekie, or in the hundreds of thousands, as in Crested and Least Auklets. Nineteen of the 22 species can be found in medium to large colonies, although most of these also occur in small groups, infrequently as loose aggregations or scattered pairs, as in the Dovekie and the Black and Pigeon Guillemots, or rarely solitarily, as in the Black and Spectacled Guillemots and the Rhinoceros Auklet. Only one species, Kittlitz's Murrelet, is truly non-colonial, breeding in solitary pairs. Craveri's Murrelet probably occurs most often in loose aggregations and scattered pairs, whereas the Marbled Murrelet seems to breed mainly in loose aggregations, only occasionally as isolated pairs. In summary, most alcids are colonial, with 14 of the 22 living species truly colonial; six intermediate, either loosely colonial or forming colonies at least occasionally; one in loose aggregations and sometimes in isolated pairs; and one solitary.

This high level of sociality within the family has led to many special forms of behaviour and habits. It has generated considerable interest in the group from biologists, particularly evolutionary and behavioural ecologists, regarding the evolution of colonial breeding and the development of social signals and intraspecific characteristics that allow auk species to reproduce successfully in large, often dense, single- and mixed-species colonies. Although the factors responsible for the evolution of coloniality in

The Common Murre is one of very few alcids that occur in both Atlantic and Pacific Oceans. The bill shape of alcids provides an excellent indication as to their type of diet. Whereas the short, stubby, but relatively wide, bills of some species reveal that they are primarily plankton-eaters, the Common Murre's long, slender, pointed bill marks the bird out immediately as a fish-eater. This feature, together with the streamlined head, longish neck, and brownish black and white plumage, all combine to give the species a distinguished, rather elegant, appearance.

[*Uria aalge*. Photo: Flip de Nooyer/ Foto Natura]

the auks remain unclear, as they do for most birds living in groups, there is a clear association between degree of clumping in alcid species for breeding and the distribution of their prey. Colonial species tend to feed offshore on schooling fish or zooplankton that occur in "patches" which are unpredictable in space and time owing to their mobility, whereas loosely colonial or solitary species feed inshore on prey which are more evenly dispersed and predictable.

The assumption that colonies are located where the potential for food is high and vulnerability to predators is low seems reasonable. One obvious advantage of breeding in a colony is finding food. If prey is clumped, mobile and unpredictable, though generally abundant, current information on the whereabouts of good feeding locations can be obtained from other colony members. At small colonies, incoming food-carrying neighbours can be used by other birds either by flying off in the direction from which they have arrived or by waiting until they depart and following them out to sea. Large colonies offer even greater opportunities for finding food because the stream of birds with food flying in towards the colony is normally so dense and compact that food-rich sites can be located by simply following the "highway" of incoming birds to its source. Observations of many alcids support this information-centre hypothesis. For example, detailed studies of Thick-billed Murres, Common Murres and Atlantic Puffins all show that individual birds do not leave the colony at random, but depart in relation to the arrival or departure of conspecifics that have recently delivered food. Organized streams of auks moving between feeding areas and their colonies are known for Pacific and Atlantic colonial species, such as the Dovekie, murres, *Aethia* auklets and puffins, at both high and low latitudes, making their appearance a characteristic feature of a large alcid colony. Such behaviour can be considered essential to attaining a high performance in reproduction at a large alcid colony.

Many alcids breed in colonies with other auk species and seabirds. The immense mixed colonies of *Aethia* auklets and other alcids on the Yamskie Islands in the northern Sea of Okhotsk, probably comprise the largest and most diverse concentration of colonially-breeding alcids anywhere. The 6,000,000 Least Auklets, 300,000-400,000 Crested Auklets and 150,000-200,000 Parakeet Auklets, along with tens of thousands each of both murre species and Horned Puffins and lesser numbers of Tufted Puffins and Spectacled Guillemots, make the location very special. Single-species colonies appear to be rare, and colonies supporting 2-4 alcid species are the commonest. In general, mixed-species colonies are likely to be a consequence of paucity of suitable breeding sites (see Habitat) within range of an adequate food supply. This means that species will typically come together where oceanographic and terrestrial conditions dictate, with final species composition and numbers mainly determined by differences in the availability of species-specific breeding habitats. Competition between species for nesting space and food resources appears limited, as requirements for breeding differ, even amongst congeneric species like the murres and the small *Aethia* auklets. There may even be advantages in mixed colonies such as increased effectiveness in detection of predators and in food-finding. But, overall, most of the advantages of coloniality occur regardless of the number of auk species in the colony.

The development of social signals, their diversity and functions are intertwined with the degree of coloniality of the species. Alcid species that breed in large, dense aggregations have a larger repertoire of signals and typically a more complex array of social behaviour and relationships than those breeding in loose groups at relatively low densities. The need to communicate with mate and neighbours with clarity and speed is probably higher when breeding occurs at densities exceeding 20 pairs/m^2, as in Common Murres, than in Dovekies and puffins where nest densities are normally below 1/m^2. Behaviour within Alcidae is less ritualized than in other colonial seabird groups like the gannets and boobies, the cormorants and the gulls. A greater diversity in body size and life-history pattern in alcids may well explain the differences. Many displays exhibited in larids and sulids occur in each of the species in the family, whereas few displays are common to all auk species. Behaviour and signals of all species serve as communication pathways between individuals for exchange of information.

Social signals in alcids can be divided into sexual and agonistic behaviour. Sexual behaviour functions in pair formation, maintenance of the pair-bond, and reproduction. Since all alcids are monogamous and show high mate fidelity, behavioural processes involved with mate selection and maintenance are critical to life-time reproductive success and they are probably com-

plex. Although descriptions of the social signals used by most auk species have been made, their origins, functions and contributions to overall patterns of social behaviour are largely unknown. What is known is that considerable time is spent performing displays at or near the breeding site. Greeting displays, often in the form of mutual billing or fencing between pair members, and ceremonies are common in most species ranging from the clashing of open bills and loud calling in Common Murres and vigorous bill-vibrating and billing of Razorbills to the elaborate hunch-whistle posture and billing of the Black Guillemot. The conspicuous billing ceremony in the Atlantic Puffin, almost always initiated by the male, functions in pair maintenance but not as a greeting display. Many forms of behaviour within the pair also occur on the sea near the colony, often at the base of the cliffs where the birds have their breeding site, as is the case in Razorbills, *Cepphus* guillemots and puffins. Allopreening is highly developed in the three large alcids, most frequent in the Common Murre which breeds at the highest density, and less common or absent in the medium to small-sized auks, such as puffins, *Cepphus* guillemots and the Dovekie. Behaviour patterns and courtship signals associated with copulation are highly developed and diverse, often intense and almost ritualized, and most intricate in the auklets. These and other displays centred at the breeding site are all important in pair-bonding, copulation and defence of the site, all critical to successful reproduction.

In contrast to this, are the agonistic behaviour and displays related to territorial defence and site-ownership. These contain elements of aggression directed towards intruders or competitors for limited resources, such as quality breeding sites and mates. The territory may be the small ledge-space occupied by a pair of murres or the area at the entrance of a puffin burrow or guillemot crevice. Breeding sites are defended by both members of a pair using threat displays and fighting. Aggressive encounters are most frequent in high density breeders like the murres, but these interactions are normally of short duration and offset by highly developed appeasement displays and signals. Most confrontations between intruders and resident birds begin with ownership displays or lunges by the owner and end in retreat or presentation of an appeasement signal or posture by the intruder. Actual fighting is rare in all auks, but when it does occur it is unritualized and usually consists of spearing or grabbing the opponent with the bill, followed by twisting and turning, or strong wing-beating, and in some species such as puffins and *Cepphus* guillemots, also involves slashing with the sharp claws. Physical combat occurs when threat displays have failed or where the aggressive action arrives too quickly to permit an averting display. Fights are usually short, though some may go on for several minutes. Competition and fighting for breeding sites can result in regular fighting bouts between individuals over periods of days and weeks, rarely months.

Most threat displays in alcids are unritualized, but some may be ritualized, particularly those associated with site-ownership. For example, in the Atlantic Puffin there is a step-wise progression of events from low- to high-intensity threat displays, culminating in fighting. The progression in response to the approach of an intruding bird proceeds thus: sitting at the burrow entrance, with a low threat advertising ownership; then a neck stretch and slow head waving; standing and head waving; higher-intensity bill displays, holding the closed bill in profile towards the intruder; followed by head-flicking with the bill closed; then, finally, head-flicking with the gape and head-flick, while the bird is frozen in an upright position with maximum bill gape, the most aggressive display in the repertoire of the species, which may be followed, if necessary, by actual attack and physical combat. Display of the bill to maximize its size and potential for fighting is most important, and most interactions end before head-flicking with the open bill.

There are also numerous post-landing and ritualized walking postures in auks, including those of puffins as they land within the nesting space, a low-profile wings-raised posture that is held for 5-10 seconds before the bird moves. Where landing has been inaccurate, and the distance the bird must walk to reach its burrow is lengthy, it will often adopt a hunched low-profile posture, similar to the landing position except with the wings down, as it walks through areas of the colony occupied by breeding birds. Both these ritualized displays have an appeasement function, motivated to reduce aggression from neighbouring birds by signalling the displaying bird's presence and non-aggressive intent. Each auk species has its own set of appeasement displays and signals, but the largest repertoire occurs in the highest-density breeders, the murres, which suggests that the evolution of inter-pair appeasement signals has been closely related to breeding density.

To a lesser degree, those species in small, loosely aggregated colonies, or those breeding as isolated pairs, also display features deserving of special attention. For example, Kittlitz's Murrelet, breeding widely dispersed and solitarily on mountain scree and rocky ground, and the Marbled Murrelet, occurring as isolated or scattered pairs mainly in old-growth coniferous forests, both considerable distances inland from the sea, offer a great challenge to alcid observers. What are the principal determinants of their selection of habitat for nesting, and what factors in the marine environment are important to chick-rearing and post-fledging survival? And what behavioural patterns are associated with successful reproductive performance and how are they inter-related to those of other alcids? Knowledge of the reproductive ecology of these low-density breeders may provide considerable insight into the evolution and diversity of alcid coloniality.

Voice

The name "auk" originates from the Scandinavian root "ălka", the old Norse word describing the vocalizations or noises of some Alcidae. In general, little is known about vocalizations outside the breeding season, but the information that does exist suggests that the birds tend to be mostly silent. However, during the breeding season most alcids are vocal, with calls that can be loud and very obvious, though not highly specialized in structure or form. At breeding colonies, vocal displays are usually associated with breeding behaviour, most often as threat displays during agonistic encounters with conspecifics or potential predators, but also as integral parts of courtship and social rituals or communication between parents and offspring. Calls range from delicate soft whistles in *Cepphus* guillemots and *Aethia* auklets to loud, raucous growls and groans in murres and puffins.

Vocalizations tend to be simple in construction and diversity, separating into three broad categories: sharp single notes representing warning or distress; trilling calls involved with pair communication and bonding; and hoarse, unmelodious calls, taking the form of clucks, snarls, growls and extended series of quivering, gargling calls during aggressive encounters, varying in intensity, frequency and amplitude according to the degree of involvement. Studies of voice in auk species are limited, but males seem to be more vocal than females, probably related to the male's dominant function in the acquisition and defence of the breeding site. The groans of two male puffins, with bills locked together, pulling and twisting, in a dispute over ownership of a burrow or the high-pitched growls of two murres in combat, spearing and sparring with their long and pointed bills, for possession of a small space on a rock ledge, leave little doubt as to their threat-aggression component. In contrast are the soothing and melodious whistles of Black and Pigeon Guillemots sitting at the entrance to their rocky nest crevice early in the breeding season or the trilling calls of Dovekies performed at the colony by flying or sitting birds, often involving the simultaneous participation of large numbers of birds. The social functions of these mass vocal displays are poorly understood.

Characteristic calls are produced between breeding birds and their chicks, some unique and distinct to facilitate parent-chick recognition, others to communicate immediate needs such as brooding and feeding. Chicks generally make plaintive, high-pitched, monotonous calls when soliciting food, apparently most pronounced in cavity- and burrow-nesting species where parent-chick recognition is limited or absent and where there is no parental care after fledging, for instance in puffins and *Cepphus*

The Thick-billed Murre, a species very similar to the Common Murre in both appearance and breeding requirements, occurs at more northerly latitudes, although their ranges do overlap somewhat. Exclusively marine at other times, it only comes to land in the breeding season, forming sometimes vast colonies, on sheer, inaccessible coastal cliffs and rocky islands, where narrow ledges offer adequate nesting terrain, where ground predators such as foxes are absent, and where adequate food supplies for feeding the young are available from nearby waters; in addition, these must be ice-free early enough in the summer to enable the birds to complete their breeding programme in about two months.

[*Uria lomvia lomvia*, Bear Island, Barents Sea. Photo: Tui De Roy/ Auscape]

guillemots. The loud, distinctive calls of adult murres searching for their chick after becoming separated on a crowded ledge or at sea after fledging, and the corresponding wailing distress cry of a lost chick, underline the significance of vocalizations that are individual-specific and easily identified at a distance. These calls function to reunite separated family members and enhance chick survival and productivity of breeding pairs; they are found in species breeding at high densities where parents and young can become separated and where there is prolonged parental care after fledging, for example murres, the Razorbill and *Synthliboramphus* murrelets.

Overall, auks are highly vocal during the summer at the colony, mostly when on land but also to a lesser extent on the water and in flight. The degree of vocalization and extent of repertoire are highly variable between species, but are generally most pronounced and developed amongst species breeding in large colonies, notably the Dovekie, *Aethia* auklets and murres. Certain species are less vocal than others during breeding and have a smaller number of calls, for example puffins; some appear to be mostly silent, for example *Brachyramphus* murrelets. The magnitude and functions of calls are imperfectly known for all species. Although quantitative data and details of vocal repertoire are unavailable for any single species, partial quantitative analyses have been made of some species including the Dovekie, Common Murre, Razorbill, *Cepphus* guillemots and Atlantic Puffin.

Food and Feeding

Feeding habits are extremely diverse among the Alcidae. Diets span all the trophic levels between plankton-feeding and exclusively fish-eating, and foraging occurs over the entire neritic zone, from near-shore to offshore in the deep ocean, and at variable depths from middle upper waters to on, or close to, the sea floor. Members of the family show impressive ecological segregation and dominate other species-groups within their range in relation to number of species and biomass. Other co-existing marine groups, especially shearwaters and petrels, gulls and terns, and to a lesser extent gannets, cormorants and pelicans, are either surface-feeders (which auks are not), or so markedly different in body form and specialization that the potential for interactive, competitive relationships is minimal. The auks stand out from other marine bird groups in the Northern Hemisphere by the adaptive radiation they have achieved within the broad and ecologically diverse sub-surface water zone of the northern oceans, which makes their study both exciting and stimulating, particularly in relation to food and feeding.

Auks obtain all their food from the sea, by diving from the surface and propelling themselves under water with their wings, in pursuit of prey. They are all solitary feeders, capturing and swallowing their relatively small prey individually, mainly while swimming in the water chasing mobile prey, but sometimes at the sea bottom in the case of *Cepphus* guillemots. Individual alcid species are plankton-feeding specialists, fish-feeding specialists, or intermediate generalists feeding on both plankton and fish. Apart from the conspicuous gradation in body size, from small in plankton-feeders to large in fish-eaters, which corresponds to increasing prey size, the size and shape of bills also differ according to feeding adaptation. The small plankton-feeders have short, stubby bills whereas those of the fish-eaters are generally longer and larger. In addition, the six true plankton-feeders have gular throat pouches used for storing and carrying food to their young, a specialization for long distance foraging.

The true plankton-feeders comprise the Dovekie, Cassin's and the Parakeet Auklets, and the *Aethia* auklets, all of which are known to feed throughout the year on planktonic herbivorous crustaceans, particularly the calanoid copepods *Calanus* and *Neocalanus*, the euphausiids *Thysanoessa*, and amphipods *Parathemisto*. The five auklets share this niche in the North Pacific, with ranges that overlap in boreal waters, but only one of these species, Cassin's Auklet, has a range that extends south into cool subtropical waters. The ecological equivalent of the five Pacific auklets is limited to a single species in the Atlantic,

the Dovekie. This difference in number of plankton-feeding alcids between oceans corresponds with the greater diversity and total biomass of macroplankton in the Pacific, as does the diversity of plankton-feeding whales and other marine vertebrate groups.

The bill and tongue are variable and distinct in each of the three feeding groups. The plankton-feeders, which prey mainly on small, soft-bodied crustaceans, have a relatively wide bill, a broad tongue that is thick and fleshy, and a broad palate covered with numerous denticles. The flexible and muscular characteristics of the tongue allow small food items to be handled with ease after capture, and held in place against the upper palate until the bird is ready to push them into the gular food pouch; only the soft, strong, flexible tongue shown by all *Aethia* auklets could accomplish this. The fish-eaters, on the other hand, normally prey on hard-bodied, fast-swimming pelagic fish that must be caught and manipulated with speed and precision. To achieve this, the fish-eating auks have a narrow, sharp-tipped bill with a long, partially cornified and rigid tongue that is encased in a deep trough formed by the horny sides of the lower mandible, and a narrow palate with sharp regularly spaced denticles for pinning prey effectively. Together, these features ensure robust, vice-like leverage of the tongue onto the roof of the mouth when holding large, mobile prey, a tendency most pronounced in the Common Murre and the Razorbill, but also well displayed by *Cepphus* guillemots. Between these two extremes lie the more generalized fish- and plankton-feeders, the puffins, the Rhinoceros Auklet, and the murrelets. These species show characters of the bill and tongue that are intermediate, though variable between species, but all with relatively broader bills and tongues than the species feeding almost exclusively on fish, and with the distribution pattern and density of palatal denticles mid-way between those of the fish- and plankton-feeding alcids.

Although the family exhibits trends in body size and structure of the bill and tongue that seem to be food-related and important to ecological theory, its relatively high species diversity and close interspecific relationships indicate a reasonably high degree of overlap in food habits. Since most information about diet comes from studies of food delivered to chicks during the breeding season, knowledge of what adults eat is generally limited, as is true of the winter diets of all age groups. We know little about actual foraging ranges of pelagic auks, and even less about their behaviour once they have discovered prey. To what depths do individual species normally dive and feed, for what durations of time, and at what energetic costs? Is segregation achieved between the three broad feeding groups and among closely related species within each group by differences in niche exploitation in time and space? Are species mainly separated by position in the water column rather than by prey type? These and numerous other questions abound, many that will remain unanswered, simply because the ocean is vast and our abilities to observe auks at sea are very limited. While these gaps in information seem enormous, particularly when compared with what is known about feeding relationships in terrestrial avian communities, great advances have been made over the past 20-30 years. Doubtless much more information is required to answer the cutting questions of adaptive radiation in Alcidae, but an examination of some of the highlights of what is known of the feeding and foraging habits of the Alcidae may be revealing.

Auks do not find their food at sea by random search. Oceanographers have known for decades that plankton is not uniformly abundant over all parts of the sea, nor are the standing stocks of macroplankton and nekton in the upper surface waters. High primary and secondary production are associated with zones of intense mixing of water masses, and it is in these regions of upwelling and convergences, as well as "downstream" from them, that phytoplankton and zooplankton become especially concentrated at convergent fronts and tidal rips of dissimilar water types. This patchy distribution of prey, makes it necessary for the birds to reside in or close to these food-rich areas throughout the year, in winter for self-maintenance and survival, and in summer to meet the extra demands of reproduction. These places may be widely separated, often by thousands of kilometres, making it necessary for staging areas between the two to enable successful migratory movements in spring and autumn. Requirements for breeding are particularly demanding, making it necessary to have sufficient food of the correct quantity and quality available at the right time and place for egg formation, incubation and chick-rearing. Choice of place is especially important for the true plankton-feeding alcids that can only feed effectively where their prey occurs at high concentrations. This perhaps accounts for the enormous colonies of such plankton-eaters, like Cassin's, Crested and Least Auklets in the Pacific and the Dovekie in the Atlantic.

Concentrations of alcids are almost always found in association with major areas of upwelling, systems that are often patchily distributed in space and well offshore away from breeding locations. In many regions of convergent fronts and current rips there are distinct water masses with steep temperature differences causing opposing water movements and sinking. All of these physical properties and temperature gradients at or near the sea surface contribute to high concentrations of zooplankton and fish. At high latitudes in Arctic regions, massive local concentrations of plankton often form in places that show vertical mixing of waters with differing salinities, such as the enormous dilution produced by the introduction of glacier melt-water into surrounding seas. One example is the Devon Ice Cap at the northern entrance to Lancaster Sound, Canada, where millions of Dovekies from colonies in north-west Greenland occur each spring and early summer to exploit the high-density zooplankton patches that cover an area about 110 km long by 24 km wide along the south-east coast of Devon Island. This area of water, roughly 400 km distant from the Dovekie colonies, seems an important if not essential food source for most of the 30,000,000 pairs of Dovekies during their energy-demanding period of egg formation and initiation of breeding in late May and June; it is also used later in the season, particularly in August during chick-rearing and fledging. Similar "hot spots" have been noted elsewhere in low and high Arctic waters, as they have been too at lower latitudes around convergences and upwellings of cold and warm water masses. But only more detailed oceanographical studies of the regions known to have large concentrations of colonially-breeding auks will reveal the general correspondence and biological significance of these dynamic water systems and details of their exploitation by local breeding populations of Alcidae.

The main prey of the plankton-feeders comprises planktonic crustaceans, principally copepods, euphausiids and amphipods. Seasonal changes occur in the diets of most species, often reflecting differences in availability over time and, in some cases, availability and the relative nutritional values of individual prey species. In the high Arctic, Dovekies feed mainly on copepods early in spring during May and June, but switch largely to amphipods and larval fish when rearing young in July and August. In north-west Greenland the change coincides with the increased availability of larger stages of the free-swimming *Parathemisto*, amphipods with a caloric value significantly higher than the copepods. The summer diets of all the *Aethia* auklets and Cassin's Auklet also comprise planktonic crustaceans. Crested Auklets feed mainly on *Thysanoessa* euphausiids with lesser amounts of amphipods and large copepods, and Whiskered and Least Auklets concentrate on *Neocalanus* and *Calanus* copepods supplemented by some euphausiids, the latter often dominating the winter diet of all three auklet species. Cassin's Auklets feed heavily on euphausiids, amphipods and copepods alike, in proportions varying with time and location, and they appear to select large copepods (*Neocalanus cristatus*) over smaller ones (*N. plumchrus*, *Eucalanus bungii*) when both types are present; they also take some squid and fish, such as sandlance or sandeels (*Ammodytes*) and sculpin. Parakeet Auklets have a more diverse diet than the *Aethia* and *Ptychoramphus* auklets, feeding largely on hyperiid amphipods (*Parathemisto*) and euphausiids (*Thysanoessa*) early in the season, and copepods (*N. cristatus*) later, supplemented by numerous decapod larvae, gelatinous zooplankton (ctenophores, jellyfish), immature fish such as sandeels and walleye pollock, and fish eggs. This broad diet with considerable exploitation of fish larvae and eggs is believed to explain why the species is so abundant in the south-eastern Bering Sea and along the shallow coastal inner shelf regions where primary production and zooplankton biomass are normally low. After breeding, the euphausiid *T. inermis* becomes the principal

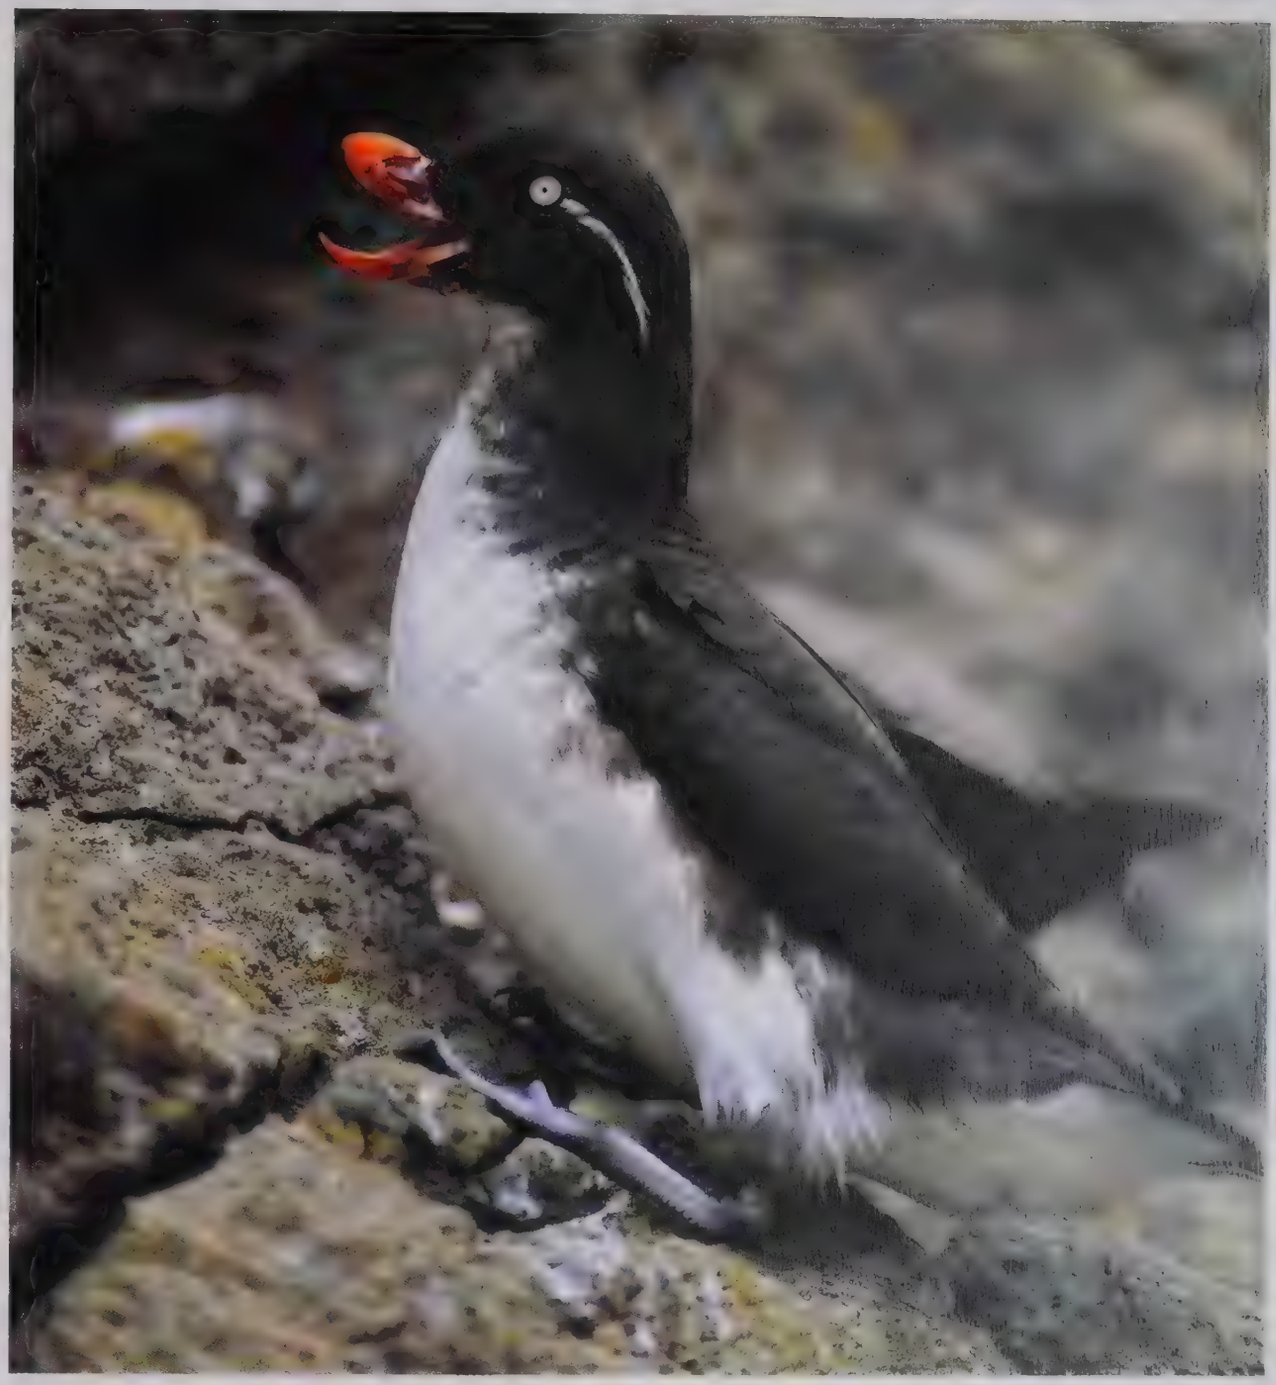
The Horned Puffin, the Pacific counterpart of the Atlantic Puffin (Fratercula arctica)*, is very similar to the latter in both appearance and general habits. More abundant at the higher latitudes of its breeding range, it is largely sympatric with the Tufted Puffin, with which it may compete for nest-sites. Like the majority of the alcids it forms vast breeding colonies at times, the size depending on the availability of nesting sites, which are typically in crevices and cracks in rocks and scree and under boulders, and less often in burrows on grassy slopes. In its social behaviour, displays are various: "Head-jerking" on the part of the male may take place before copulation, but is also performed on other occasions, rarely by both members of a pair. "Billing" occurs throughout the breeding season and indicates pair-bonding: in the Horned Puffin it frequently follows a bird's landing near its mate at the nest-site. The two birds slap the lateral surfaces of their bills together, such displays lasting perhaps 2-3 minutes. The main threat display is "Bill-gaping" when the bill is pointed towards the opponent wide open, while in the "Landing Display" the wings are held high and the tail cocked, probably to show appeasement by signalling lack of aggressive intention when a bird is landing or walking through the colony.*

[*Fratercula corniculata*, Alaska, USA. Photo: J. J. Alcalay/Bios]

food of many auklet species during autumn and winter, best exemplified by the Whiskered Auklet with a winter diet containing at least 90% *T. inermis*.

Most auks have a varied diet, even though invertebrates or fish alone are predominantly eaten for much of the year or at certain times. For example, only Whiskered and Least Auklets can be described as almost exclusively planktivorous, as small or larval fish do occasionally appear in the diets of adults or chicks of Dovekies and Cassin's, Parakeet and Crested Auklets. The other species are either primarily fish-eaters or species that consume significant quantities of both fish and zooplankton. Although the Thick-billed Murre, Razorbill, *Cepphus* guillemots, Rhinoceros Auklet, Atlantic and Horned Puffins feed mostly on fish throughout the year, euphausiids and other crustaceans, squid or polychaete worms normally supplement the birds' diets during the non-breeding season. The Common Murre comes closest to being an exclusive fish-eater, but even in this species the winter diet regularly includes small quantities of crustaceans. The dominant summer foods of the piscivores vary between species and water type. In the Arctic, Thick-billed Murres take demersal species like Arctic cod (*Boreogadus saida*), the dominant small fish in high Arctic waters, supplemented by sculpins (Cottidae) and blennies (Pholidae, Strichaeidae, Zoarcidae), and a wider variety of prey farther south including pelagic capelin (*Mallotus villosus*). The other large auks, the Common Murre and the Razorbill, along with the medium-sized Rhinoceros Auklet and puffins, feed principally on pelagic shoaling fish such as clupeids, sandeels and capelin. The *Cepphus* guillemots feed mostly on sculpins and blennies in the near-shore coastal waters.

The murrelets, in turn, display summer diets encompassing zooplankton and fish. Both Marbled and Kittlitz's Murrelets take euphausiid crustaceans (*Thysanoessa spinifera*) from late winter to early summer, with mostly sandeels (*Ammodytes hexapterus*) and smaller amounts of herring (*Clupea harengus*), capelin and shiner perch (*Cymatogaster aggregata*) and certain smelt (Osmeridae) through the remainder of the breeding season. Xantus's and Craveri's Murrelets are predominantly fish-eaters, usually foraging over deep water rather than in shallow coastal regions. Xantus's appears to feed mainly on larval northern anchovies (*Engraulis mordax*) supplemented by Pacific saury (*Cololabis saira*) and rockfish (*Sebastes*), while Craveri's feeds largely on larval rockfish and herring, as well as adult lanternfish (*Benthosema panamense*), euphausiids and squid. The remaining two *Synthliboramphus* species, the Ancient and Japanese Murrelets, feed on roughly equal amounts of euphausiid crustaceans and small larval fish. The Japanese Murrelet takes mainly crangonid shrimps (*Sabinea*, *Sclerocrangon*) and herring and saury (*Hypoptychus dybowskii*), sandeels, smelt and sculpin (*Triglops*). Ancient Murrelet diet varies between regions, but mainly comprises euphausiids (*Thysanoessa spinifera*, *T. pacifica*, *T. inermis*) with lesser amounts of fish including small sandeels, shiner perch, rockfish, capelin, walleye pollock (*Theragra chalcogramma*), smelt and sculpin.



Little is known about the diving depths to which alcids regularly descend in search of prey. Measurements of time intervals between initiating a dive and reappearance at the surface provide some indication of potential maximum depths attained, but these rely on assumptions of speed of descent and proportions of total time under water spent diving and foraging at a constant depth. A combination of incidental drownings of auks in fishing gear at known depths and small depth gauges attached to free-living birds have provided valuable insights into actual maximum depths. These findings also show a close correspondence between diving depth and bird body size, larger birds diving deeper and more often than smaller species. The murres are the deepest divers, probably attaining depths greater than of 100 m regularly, whereas the Razorbill and medium-sized auks, puffins and Rhinoceros Auklet likely forage mostly at depths of 20-40 m, and the smaller plankton-feeders normally above 20 m, rarely deeper than 30 m. The Black Guillemot, though restricted to shallow inshore habitat when breeding, probably dives to considerable depths when farther offshore in winter. The amount of time spent foraging at different depths is poorly known for all species, as are the cues used by the birds to assess the food potential of any given water area. We do know, however, that the larger auks dive for longer periods and beat their wings at a higher rate than other species, which is probably reflected in both rate of descent and depths achieved. The *Cepphus* species are unusual in that they use their feet as well as their wings when swimming along the sea floor; this is most likely an adaptation for their bottom-feeding habits, enhancing their ability to maintain a position and probe the benthos effectively.

The foraging distances of breeding auks vary over a wide range. The murres, Dovekie, *Synthliboramphus* murrelets and *Aethia* auklets may travel lengthy distances for food, 50 km or more, with the Razorbill, Rhinoceros Auklet and puffins also flying similar distances but more often feeding closer inshore. Although the coastal *Cepphus* guillemots may forage close to shore, they can travel long distances to bays and other sites where food is abundant. The inland-breeding *Brachyramphus* murrelets often fly long distances over land from their nests to reach the sea, most flights covering about 20 km, but sometimes as much as 75 km; however, they usually feed within 1-10 km of the shore in shallow waters adjacent to their nesting site.

The manner of carrying and delivering food to the young shows remarkable variation. In the true plankton-feeders, like the Dovekie and Least Auklet, both parents feed their young on small crustaceans, mainly calanoid copepods, transported from often distant feeding areas back to the colony in their specialized distensible gular throat pouch. Food items in a meal may be 1-17 mm long and are given to the chick as a mucous-covered package or "soup" typically containing 400-600 individual prey items weighing a total of 3-8 g. About 5-8 meals are delivered to a chick each day, with no differences in frequency of feeding or meal size carried by male and female parents.

In contrast are the fish-eating murres, Razorbill and puffins. On each journey, Common and Thick-billed Murres feed their chick a single fish which they carry back to the colony lengthwise in the bill with the head deep inside the mouth and tail forward, which may allow partial digestion of the bony head before it is given to the chick. The number of chick meals delivered daily by a pair of Common Murres varies at 3-8, the total weight averaging 28 g of pelagic schooling fish like capelin, sandeels or sprat (*Sprattus sprattus*), and each fish about 100-140 mm long. Thick-billed Murres at high latitudes feed their young predominantly Arctic cod in a manner and at rates similar to those of Common Murres, but the total daily amount of fish consumed is higher, at about 58 g. Razorbills and puffins usually carry two or more immature fish crosswise in the bill, mostly capelin, sandeels, herring or sprat depending upon geographic region, with the number of fish per meal decreasing with size of fish caught. Daily provisioning rates to chicks by both parents equally are of 2-9 meals, with average total amounts of food delivered daily varying from 20-25 g in the Razorbill, to 43-62 g in the Atlantic Puffin, 24-72 g in the Horned Puffin and 16-80 g in the Tufted Puffin. When more than one of these fish-eating species is rearing young on the same prey at one colony, average sizes and numbers of fish taken usually vary between the species: for example, Common Murres deliver one large item, Razorbills a few medium-sized ones, and Atlantic Puffins many small ones. The *Cepphus* guillemots specialize on small, benthic fish such as sandeels, gunnels (Pholidae), pricklebacks (Stichaeidae), eelpouts (Zoarcidae), sculpins and rockfish. All three species take similar-sized fish which both parents deliver to their 1-2 chicks, normally one fish at a time held crosswise in the bill, with 3-15 meals daily.

Little is known about the feeding habits of the Great Auk, and there are obviously limited prospects of learning more about this unusual, large flightless alcid, now extinct for over 150 years. However, examinations of bill measurements in relation to today's fish-eating alcids, especially the Great Auk's closest extant relative the Razorbill, suggests maximum and preferred prey weights of at least 100-150 g and 30-40 g respectively for this species. Detailed observations of the Great Auk at sea, given in the *English Pilot* of 1767, indicate a typical offshore feeder, probably foraging most often on benthic fish prey in waters of 75 m or less, sometimes at greater depths. It probably had a foraging range stretching at least 60-70 km from the colony,

Outside the breeding season alcids tend to be rather silent. During breeding most vocal displays are associated with some aspect of breeding behaviour, though many are still of uncertain interpretation, maybe used in threat displays to deter rivals or intruders, forming a part of courtship and pair-bonding, or purely a means of general social communication. In the breeding season, the Parakeet Auklet has been noted as being very vocal close to its nest-site. It has a call uttered from land or water which may be provoked by the approach of danger, or can be given before the bird takes flight. One observer remarked that a mated bird would land near the nest and utter a trilled song until its partner arrived, when a duet would ensue. At other times a single bird, sex unspecified, gives voice from a perch as in the case of this Parakeet Auklet. During this vocalization, the significance of which is again unknown, the neck is stretched somewhat, the bill is opened, and the head tilted up briefly.

[*Cyclorrhynchus psittacula*, Alaska, USA. Photo: Winfried Wisniewski/FLPA]

possibly even as much as 110 km based on comparisons with the similar-sized Macaroni Penguin (*Eudyptes chrysolophus*), and normally fed inside the continental shelf or shelf slope areas. Some support for these proposals comes from the direct evidence that remains of the Great Auk's diet, the food content of birds collected in south-west Greenland around 1770; this comprised short-horn sculpins (*Myoxocephalus scorpius*) and lumpsuckers (*Cyclopterus lumpus*), both largely bottom-dwelling fish.

It has recently been suggested that young Great Auks were fed mainly planktonic crustaceans carried back to the colony by the parent in the gullet and regurgitated. But the morphology of the Great Auk's mouth and bill, combined with its overall body size and structure, suggest instead feeding habits similar to the other large Alcidae. It seems more likely that this flightless 5500-8000 g alcid probably fed on both pelagic schooling fish and those on or close to the sea floor by diving, possibly transporting large fish catches back to the colony within its greatly expandable proventriculus, much in the manner of penguins and gannets. Unfortunately, of necessity this all remains highly speculative, as this remarkable species has been lost for ever.

Breeding

Most alcid species breed in colonies on islands and sea cliffs along rocky coasts. Colonies vary in size, from a few scattered pairs like the low-density breeding inshore *Cepphus* guillemots to more than a million birds like the gregarious Dovekie or Least Auklet. Two species, Kittlitz's and the Marbled Murrelet, are non-colonial, both nesting considerable distances inland, up to 75 km from the sea coast. Kittlitz's nests on rocky mountain slopes, the Marbled usually high above the ground on branches in the upper canopy in old-growth coniferous forests. The other 20 species occur in small to large aggregations in single- or mixed-species colonies on offshore islands, almost always facing the sea or in close proximity, in a wide range of terrestrial habitats free of mammalian predators. Generally, most colonial alcids breed either on or in rocky substrates, earthy burrows, or in holes and cavities in sandy loam, exposed tree roots and logs.

Nest descriptions exist for all species, even though the reasons and processes involved in their selection are poorly understood for many species. In a few species only a small number of

nests have been found, for example in Marbled, Kittlitz's, Xantus's and Craveri's Murrelets.

The range of breeding habitats used by Alcidae is considerable, and some species have very specific habitat requirements for breeding while others are more adaptable. The *Cepphus* Guillemots normally choose fissures or crevices in rocky cliffs or boulder fields, but also make use of abandoned burrows of other species, and cavities provided by human artifacts such as discarded barrels or other abandoned structures. In contrast, the largest species, the Thick-billed and Common Murres and the Razorbill, breed mainly on rocky cliff ledges, murres mostly in the open but sometimes in crevices or caves, and Razorbills usually under partial cover; all three also occur on expansive rock areas and on flat, low-lying isolated islands, Razorbills most often in boulder fields and rubble. Ledges occupied by the Thick-billed Murre have been found to show very specific site characteristics including width and slope. Puffins and the Rhinoceros Auklet nest in burrows that they excavate in the ground on maritime slopes, likewise showing highly specific habitat requirements; Atlantic and Tufted Puffins normally select grassy maritime slopes where the ground has certain characteristics of texture, integrity and angle of slope. The Horned Puffin commonly nests in rock crevices or fissures on sea cliffs or slopes, and the other three species do so less frequently, while the Rhinoceros Auklet will also use the bare forest floor of thickly forested islands. The four colonial small murrelets use cavities and hollows around root systems of trees, logs or rock crevices for breeding sites, while the Ancient and Japanese Murrelets also excavate holes in soft ground. Dovekies and most of the small auklets nest most often in sea-facing scree slopes and boulder fields, Dovekies also often on precipitous cliffs and auklets in rock rubble along coastal beaches; again, detailed examinations of the scree slopes chosen reveal numerous species-specific microhabitat preferences, as is the case for most auk species. Selection of breeding habitat is critical in all alcid species, and there is a gradient of quality within a species' range. Where examined, for instance in the Atlantic Puffin, high quality habitats where breeding performance is highest are usually occupied by the largest males, but not females, which suggests a competitive advantage related to male body size, probably important to success in aggressive encounters and breeding site acquisition.

All auk species are marine, coming to land only to breed, being otherwise totally independent of it for feeding, resting and sleeping. Certain other features are common to all members of Alcidae: they are long-lived, many of the medium-sized to large species like the Common Murre and Tufted Puffin reaching ages well over 20 years; they reach sexual maturity slowly, most at around 4-5 years of age, for instance the murres, Razorbill and puffins, but others like the *Cepphus* guillemots at 3 years; and they have low reproductive rates, normally with a single-egg clutch except in *Cepphus* guillemots and *Synthliboramphus* murrelets which usually lay two eggs, and correspondingly slow recovery rates. These life history characteristics make all auks vulnerable to natural or man-induced disturbances that reduce their numbers owing to their relatively low fecundity. For example, a 50% population reduction in a cormorant (Phalacrocoracidae) might show complete recovery within 4-5 years, whereas an auk might require 20-25 years to do so, everything else remaining equal.

Adult annual survival is known for 10 of the 22 alcid species. Estimates range from 75% for Least Auklets and 77% for Ancient Murrelets, both relatively small species, to 89-95% in the larger murres, Razorbill and Atlantic Puffin. Most species probably breed once annually, though Cassin's Auklet sometimes lays a second clutch after successfully fledging the first chick, and only about 50% of Spectacled Guillemots seem to reproduce each year. In general, adult life history characteristics are incompletely known and require additional study.

Most alcids return to their colonies several weeks, sometimes months in boreal water regions, before initiating egg-laying. This pre-laying period is used to make the transition from a sea existence to one that is land-based, the birds performing activities that include repossession and occupancy of breeding sites, re-establishment of pair-bonds, mating and preparation of the site for an egg, which for burrow- and crevice-nesters can be demanding work. The time available for completing these tasks is shortest in northern regions where the whole area may remain covered with ice and snow until late spring or early summer. In temperate regions, birds may spend 4-8 weeks on or near the colony before the first egg is laid, some species even longer, like the Common Murre which at certain British colonies reappears 4-5 months before breeding, or Cassin's Auklet in southern parts of its range where night-time visits to the colony occur throughout the non-breeding period. But 3-5 weeks is the norm, and colonial birds typically display a cyclical and normally synchronous pattern of colony attendance during this period, with all birds present for 3-5 days followed by an equal time period when the colony is deserted. Although features of this attendance pattern vary between species, its occurrence is conspicuous among all colonial auks. It is believed to be associated on the one hand with the need for the re-establishment of individuals at the colony in the presence of conspecifics, for site occupancy, defence and pairing, and on the other with a distant supply of food early in the season, birds typically fasting when together at the colony during this settlement period.

Fidelity to colony and breeding site are high. Results of ringing studies show that most alcids return not only to the same colony year after year, but also to the same breeding site. At one British colony, 96% of Common Murres ringed as breeders returned the following year, and of those that did, 90% used the same breeding site. Similar strong attachments to the colony and site have been recorded for Razorbills, Black Guillemots, Xantus's Murrelets, Least Auklets and Atlantic Puffins, with other species likely to show the same levels of fidelity to colony and breeding site.

Mate fidelity, or monogamy, is also the rule in all auks, birds remaining together as pairs through their entire breeding life. Not all species have been studied, but those that have indicate high mate fidelity with a corresponding low divorce rate, about 7% in Black Guillemots and Atlantic Puffins, though somewhat higher in Crested Auklets at 24%. Divorce seems to be associated with low or failed breeding performance. Co-operation between male and female partners in producing and raising offspring successfully seems likely, and in Cassin's Auklet and other species mate retention has been demonstrated to have a highly positive influence on breeding performance by enhancing both hatching and fledging success. Some species, however, may exhibit distinctly non-monogamous forms of behaviour such as extra-pair copulations in Common Murres and puffins, usually males attempting to mate with any unattended female nearby. Mate guarding is therefore prevalent in most species, each male staying close to his female during her fertile period and vigorously attacking any intruding male. Although such defence is effective most of the time, successful rapes do occur, particularly among species that mate on exposed breeding sites at high density.

Copulation usually takes place at or near the breeding site, in the open, as in Dovekies, murres, Razorbills, *Cepphus* guillemots and murrelets, less often on the sea, as in *Aethia* auklets and puffins. Mating takes place quickly, lasting only 15-30 seconds, but occurs frequently each day during the pre-laying period. In Atlantic Puffins, intense courtship displays occur on land near the burrow entrance, mostly involving repeated bouts of billing initiated by the male, and often developing into ritualized head-flicking and sky-pointing by the male. Attempts by the male to mount at this point may occur, but are invariably rejected by the female, and usually the partners simply depart together for the sea at the base of the cliffs where they copulate before returning to the colony. Some small auklets show elaborate courtship displays prior to copulation. In Least Auklets this includes a high-intensity rodent-run display, the male running in a circle round the female while in a low-hunched posture, continuously emitting a "chattering" vocalization. Copulation in Dovekies is always preceded by numerous bouts of head-wagging and billing. This period before laying is, in most colonial species, a frenzy of site defence and mating activity.

Timing of breeding is crucial to success in reproduction among the auks. For birds with a low reproductive rate, producing a single clutch of only 1-2 eggs each year, the time of laying

A flock of flying Dovekies fills the sky dramatically near a breeding colony on Spitsbergen. Such colonies can be immense, in some cases containing more than a million individuals. The Dovekie is estimated to be the most abundant auk in the Atlantic, with most colonies sited in the remote far north on mountain scree slopes that offer abundant nesting sites, where nearby offshore waters provide an abundant plankton-rich food supply, and where ground predation is minimal. One of the great advantages of living in a large colony is that information regarding the location of good feeding areas is readily available. The constant dense stream of birds flying into a colony carrying food serves to indicate to others bent on seeking food the general direction in which they might go. They have only to fly in the opposite direction to the incoming "traffic" in order to find where it originates. Studies of certain alcids confirm that birds do not leave the colony on a random search, but that their departure is related to others that have either recently arrived with food or have just departed in search of it. It is this incessant toing and froing of masses of birds between the colony and feeding sites, with all the attendant hubbub, that makes a really large auk colony such an impressive spectacle.

The Common Murre feeds extensively on fish, although it also takes some invertebrates. When searching for food it dips its head just below the surface and, once prey has been located, dives down after it directly from the surface. Normally it dives only to depths of 10-30 m, but dives to 60-70 m are known to occur regularly, while exceptionally the species has been recorded down to 180 m. Food brought to the chicks consists almost exclusively of fish, especially capelin, herring, sprat and sandeels. Only one fish is carried at a time, held head-first and lengthwise in the bill.

is all-important. The general rule is to time egg-laying so that young are reared when food is most abundantly available for them. Most alcid species do appear to lay eggs in relation to the average seasonal peak of food availability. This is most pronounced in cold water systems where prey diversity is low, which provides better opportunities for examining links between timing and prey abundance. One of the clearest examples is the Atlantic Puffin in the low Arctic and boreal waters of the north-west Atlantic. Here, laying (and therefore hatching 42 days later) by puffins in the Gulf of Maine takes place about 4 weeks earlier than at colonies in south-east Newfoundland and 8 weeks before those in southern Labrador. Examination of the timing of arrival of the principal fish that breeding puffins feed to their chicks in each of these areas shows it to correspond with peak hatching. Puffins in Newfoundland and Labrador time their breeding schedule with the influx of capelin inshore into coastal upper waters for spawning, which occurs 4 weeks later in Labrador than Newfoundland, whereas Gulf of Maine puffins focus on herring movements which occur 4-8 weeks earlier. The influence of food on timing of breeding in auks, fish- and plankton-feeders alike, is well established for many species, as are the consequences of not rearing young when food is most abundant. Young hatched at peak of food availability normally grow faster, fledge earlier and in superior condition (heavier, with maximum feather development) than chicks hatched late which usually depart prematurely in poor condition, if they survive to fledge. Although food is probably the ultimate factor controlling the timing of laying in auks, the close correspondence between sea surface temperatures and time of breeding in all alcid species suggests that sea temperature affects timing of food availability and probably serves as an important proximal cue for the birds, either alone or in combination with others such as day length.

Auk eggs are large for the size of the birds, ranging in weight from 18 g in the Least Auklet to 100 g in the Thick-billed and Common Murres, which represents 10-20% of female body mass. The largest eggs in relation to adult body size, at 22-23%, are those produced by the *Synthliboramphus* murrelets, species which have precocial chicks. The eggs range in shape from pyriform to ovoid with colours and markings that are highly variable between species, from mainly dull white with light markings in subterranean nesters, like puffins, to the strikingly bright green and blue to buff and white with conspicuous dark blotches and intricate scribbles, as in murres. Those of the two non-colonial nesters, Kittlitz's and Marbled Murrelets, are cryptic pale olive green to greenish yellow with light and dark brown spots and small blotches, to hide them in their exposed locations on the ground or, in the case of Marbled Murrelets, more frequently on lichen-covered branches. Eggs are laid on bare rock ledges in murres and the Razorbill; in rough shallow scrapes inside crevices and holes or on open gravelly substrate in the Dovekie, Razorbill, *Cepphus* guillemots, most murrelets and auklets; or on imperfect nest platforms made of grasses, twigs and feathers in the Ancient Murrelet, Rhinocerous Auklet and puffins, or of moss and lichens in the Marbled Murrelet. The usual clutch is one egg, except for species that feed inshore (*Cepphus*) or have precocial young (*Synthliboramphus*), which lay two eggs.

The incubation period is highly variable, at 41-46 days in the puffins, 32-39 days in the auklets, 32-36 in the large auks, 31-34 days in *Synthliboramphus*, 27-29 in *Alle*, *Cepphus* and *Brachyramphus*. Both parents share incubation duties, with bouts lasting from only a few hours in *Cepphus* guillemots to several days in *Synthliboramphus* murrelets. The length of time spent incubating by an individual probably also reflects the amount of time required by the off-duty bird to locate and consume food. Egg-care or attentiveness is another obvious feature during incubation. Species such as murres and the Razorbill which lay their eggs in the open rarely leave them unattended, whereas eggs under cover in burrows and crevices, or cryptically coloured, are often deserted for periods of time ranging from less than a day in the Dovekie, *Cepphus*, *Brachyramphus* and puffins, to several days in Xantus's and the Ancient Murrelets. Such behaviour lengthens the incubation period but shortens the total amount of time spent incubating by an individual bird, adaptations that may be important to energy budgets of adults, particularly by allowing more time for foraging, or as a mechanism to regulate the timing of hatching, or both. Egg neglect, the act of leaving eggs unattended, is known in at least nine alcid species and may well reflect "care" rather than "neglect" if the egg eventually hatches closer to the optimal time for rearing young than it would do otherwise. In species with two-egg clutches, incubation normally only starts after the second egg is laid to ensure that the eggs hatch at about the same time.

The Atlantic Puffin is mainly a fish-eater, but in winter the diet is supplemented with small crustaceans. It catches its prey by pursuing it under water, using the wings to propel itself forwards. If several fish are caught in a single dive and intended for the young, the puffin will stack them crosswise in its bill for easy transportation back to the nest. This species takes most of its prey fairly near the surface, and it appears that dives do not normally exceed depths of 15-20 m, although the capture of crustaceans may necessitate much deeper diving. Prey is usually obtained from waters within a few kilometres of the colony, but much more lengthy journeys may be necessary.

Hatching success, the proportion of eggs laid that hatch, is generally high in Alcidae, averaging above 70% for most species examined. Ancient Murrelets and Whiskered Auklets have the highest rates at 91% and 86% respectively, and Xantus's Murrelet the lowest at 33%, among the 19 species that have been studied. Most egg losses are caused by mammalian and avian predation. For example, the island-nesting Xantus's Murrelet loses most of its eggs to introduced black rats (*Rattus rattus*) and deer mice (*Peromyscus maniculatus*). Other factors include infertility, embryonic mortality, accidental breakage and exposure. In species breeding on cliff ledges, mostly the murres, eggs are lost as the result of parental mishandling of the egg at laying or during change-overs, causing the egg to roll off the ledge. Clutches lost early in the season are replaced in most auk species, normally within 10-20 days, though re-laying is uncommon in the three *Aethia* auklets and rare or non-existent in Ancient Murrelets and probably also in the other *Synthliboramphus* species. Replacement eggs generally have a lower rate of hatching success than those of first clutches.

Most newly hatched alcid chicks are semi-precocial, covered with thick down, and brooded by their parents until they become homoiothermic, which takes 2-10 days. Once able to regulate their body temperature, chicks are normally left alone, as both parents are away finding food for the young, except in Thick-billed and Common Murres and Razorbills, where one parent must remain at the breeding site to brood and guard the chick continuously from predators such as gulls. Chicks are usually fed by both their parents at the colony or nesting site for periods ranging from 15-23 days in the large auks to 40-55 days in Cassin's and the Rhinoceros Auklet and puffins, with the genera *Alle*, *Cepphus*, *Brachyramphus*, *Aethia* and *Cyclorrhynchus* all intermediate. The four *Synthliboramphus* species alone have a highly precocial post-hatching development pattern whereby the chicks are taken to sea unfed 1-2 days after hatching. Alcidae is unique among bird families in the diversity of its patterns of chick growth and development.

Alcid species can be divided into three groups based upon their chick development patterns. The commonest pattern is that of the semi-precocial group, which contains the Dovekie, *Cepphus* guillemots, auklets, *Brachyramphus* murrelets and puffins. All use enclosed breeding sites or have cryptically coloured eggs, and hatch open-eyed downy young that are capable of eating. The young are fed by the parents at the breeding site for 27-55 days, by which time they are well grown, at 61-111% of the adult mass; they become independent of their parents at fledging. In contrast is the precocial group containing Xantus's, Craveri's, Ancient and Japanese Murrelets, all of which are small, nocturnal species that lay two-egg clutches in enclosed sites and hatch well developed downy young with legs and feet almost adult size. The young are capable of going to sea within 1-2 days after hatching, when they are only 12-14% of adult size, but they are accompanied by their parents which guard and feed them away from land until they are fully grown. Eggs of this second group each weigh about 22-23% of an adult female, amongst the largest eggs produced by any birds relative to adult size. Species in the third group, the murres and Razorbill, are intermediate. They are diurnal and breed on exposed rocky sites where they hatch and feed their single chick for 15-23 days; at this time the chick leaves the colony for the sea, flightless and only partially grown at 20-30% adult size, but with the male parent which cares for it for the next 4-8 weeks.

These developmental patterns have evolved in relation to the availability of food resources during the chick-rearing period and the ability of the birds to exploit them. Parents with semi-precocial young can find sufficient food near the breeding site to rear them to full size, whereas those that are intermediate have food supplies that are predictable in the early stages, but likely to diminish in certainty and quantity later on, which has resulted in an early-departure strategy. Unlike these two patterns, species with precocial young are free of the colony attachment soon after their young hatch, which allows them to take the young to the food supply and move as a family group in relation to it through the period of chick growth to independence. This approach may save parents energy by eliminating the cost of flying between the food supply and breeding site. It has also allowed them to rear two chicks, something that among the other auks only the inshore-feeding *Cepphus* guillemots have accomplished. The evolution of precociality within the family and the interplay of feeding and behavioural ecological adaptations for breeding that have led to three distinct pathways to accomplish the same goal, the production of surviving progeny, are impressive. This wide range of developmental patterns

of the young in Alcidae is truly remarkable in both evolutionary and ecological contexts.

The process of departure of the young from the breeding site varies between species and developmental groups. Some species like *Cepphus* guillemots, auklets and puffins leave at night, fully developed and unaccompanied by parents. They normally fly out to sea a short distance under cover of darkness, from evening twilight to early morning, to reduce the risk of predation by gulls, both at the time of departure and later when dispersing away from the colony. Several days to a week or more before fledging, the chicks spend considerable time exercising their flight muscles by flapping their wings vigorously, either inside the burrow or nest crevice where space permits or outside close to nest-site entrance. When ready to depart, most young climb to vantage points from which they can fly off into the air or make short flights down the maritime slopes to the cliff edge where they take flight.

The murres and Razorbills, on the other hand, are flightless when they leave the colony with their male parent. Departures are usually synchronous, concentrated during the evening twilight period at which time the colonies, when large, ring with the continuous roar of the raucous calls and cries of anxious parents and young, followed by the spectacular "parachute" fluttering descents of chicks from cliff ledges, often 200-300 m high, with parents following close behind trying to maintain contact with their chick in order to avoid becoming separated and permit a quick departure from the colony immediately the chick reaches the water. Predation by gulls, and sometimes foxes, is high during departure, and unattended chicks, alone on the water or beach, are highly vulnerable. The din and commotion are no less on low-lying islands where streams of pairs of father and young move over the rocky flats and shelves descending towards the sea. Recognition of individual calls between parent and young is critical during the evening exodus where parents and young can easily become separated owing to the enormous numbers and density of birds that are involved, often thousands or tens of thousands in the case of Thick-billed and Common Murres.

In the precocial murrelets, family groups depart at night, usually a few hours after sunset, once the off-duty adult has returned. After many vocalizations by chicks and adults inside the nest, the adults emerge calling and make movements toward the sea, waiting for the two chicks to appear. Once the chicks begin their walk to the water, often scrambling or tumbling down steep hillsides and cliffy slopes, as they follow their parents, the adults fly off and land on the sea calling continuously. Chicks call as soon as they reach the sea and families reunite through mutual recognition of calls. Once together again on the water, parents and chicks immediately swim away from the colony, apparently moving several kilometres offshore before sunrise and achieving distances of 40-50 km within 18 hours after departure.

The survival of chicks to fledging varies from 66% in Crested Auklets to over 90% in Razorbills, Ancient Murrelets and Whiskered Auklets. Mortality of young after hatching is typically below that for eggs in most alcids. Major causes of chick loss prior to fledging include predation by gulls, mammals and reptiles, and food shortages causing starvation, as well as injury from conspecific adults, nest habitat destruction, and inclement weather. Post-fledging survival is difficult to measure accurately, but ringing results indicate immature survival to be low, from 15-36% for Atlantic Puffins and 30-34% in the murres and Razorbill to about 50% in Ancient Murrelets and 65% in Cassin's Auklet, the latter two both small species.

Overall, all alcids have a low reproductive rate with relatively high rates of hatching and fledging success, but a low rate of recruitment of young into the population. Although a great deal is now known about the breeding biology of the Atlantic auks and most Pacific species, it remains obvious that we lack sufficient information on variation of reproductive performance within single species and intrapopulation differences, as well as that required to make meaningful comparisons between species. All of this is required to permit better understanding of the adaptive significance of the diversity of reproductive strategies displayed by this complex and exciting family of marine birds.

Movements

Alcid migration patterns in the three northern oceans show wide divergences in movements of populations of the same species and between species and species groups or guilds. Patterns range from largely sedentary to heavily dispersive, with some lengthy and complex migrations. Pronounced differences between age cohorts of the same populations often exist, with younger birds normally moving farther south than adults away from the breeding areas into warmer waters. Many species, however, move relatively short distances away from where they breed and remain largely within their breeding ranges. At high latitudes, particularly in the northern Sea of Okhotsk, the Bering Sea and high and low Arctic water regions of the Arctic and North Atlantic Oceans, populations undergo some migratory movements after breeding owing to the development of heavy ice cover. In these cases, a general southward dispersal occurs from breeding areas to where waters remain ice-free. These autumn movements vary from comparatively slow ones, with birds concentrated at the edge of the ice where they are pushed southwards in relation to the expansion of ice cover during winter, to a rapid exodus and complete desertion of a region until the following spring. Even when lengthy, movements are normally restricted to continental shelf waters with few species moving beyond the southern limit of the boreal oceanic zone. Overall, alcid population movements tend to constitute post-breeding dispersal of adults and immatures rather than a "true" migration as performed by many other seabird groups like shearwaters, petrels, sulids and terns that travel enormous distances, often transequatorially.

Although the forms, directions and magnitude of movement within and between species populations do differ greatly within Alcidae, they all share certain features. First, post-breeding dispersal movements, whether short or long, generally tend to take birds to regions where food is more abundant or accessible, such as the Kuroshio and Oyashio Currents, the Gulf of Alaska, the California Current, the Bay of Biscay, the North Sea, the Newfoundland Grand Banks, the Scotian Shelf and Georges and Brown's Banks; for the northernmost species they also take them away from areas that become ice-covered in winter, notably the Chukchi and north Bering Seas, the Sea of Okhotsk, Baffin Bay, the Greenland and east Barents Seas, and the east and central Baltic. Second, where birds do undergo more than short distance movements, the distances travelled by young birds, especially those of the year, usually exceed those of adults. And third, the pattern of dispersal from breeding areas by most species, regardless of chick developmental type, is "downstream", following prevailing currents to wintering quarters.

Reasons for these common characteristics are simple. Changes in location due to seasonal alterations in the food supply or access to it seem straightforward: the high survival value of movements away from areas with low potential for meeting winter nutritional requirements to those known to be adequate. Differences in extent of movement between age cohorts may simply reflect differences in nutritional needs and prey composition (type and quality) or advantages gained by growing and learning necessary foraging skills in a warmer environment largely free of competition with older, more experienced birds, or both. Advantages gained by adults in remaining as close as possible to breeding areas may be related to enhanced success in re-occupation of their breeding sites, pairing, and timing of breeding. Benefits of the use of current flow patterns by almost all birds seem self-evident: reduced energy expenditure in reaching a preferred wintering area through actual physical transport by the water, and the likelihood of moving with important prey concentrations that are also being transported "downstream" from areas of high water mixing, as well as the overall associated potential for increased food availability. All auks share the need to move and forage economically, and they tend to exploit all physical and biological processes that help achieve that goal.

Patterns of movement and migration among Alcidae can be roughly divided into three basic groups. The first comprises inshore fish-feeding species that occupy distinct near-shore shallow water feeding niches and do not normally display long distance movements offshore; these are the *Cepphus* guillemots

Alone among the alcids of the Atlantic in preferring shallow coastal waters to the open ocean, the Black Guillemot is an inshore bottom-feeder, finding prey on or near the sea floor in waters of little depth. An opportunistic feeder, it takes a wide variety of fish and invertebrates. Fish are caught by surface-diving, mainly to depths of 1-8 m, although the bird may cover some distance and remain underwater for up to a minute. The chicks are fed largely on fish which the adult takes to the nest singly, held crosswise in the bill.

[*Cepphus grylle arcticus*, Norway. Photo: Uwe Walz/ Bruce Coleman]

and *Brachyramphus* murrelets. At the other extreme are the offshore fish- and plankton-feeding species that undergo relatively long distance movements or migrations and inhabit deep waters, including two planktivores, the Dovekie and the Parakeet Auklet, and seven piscivores, the Thick-billed and Common Murres, Razorbill, Rhinoceros Auklet and puffins. The third group, made up of the *Synthliboramphus* murrelets, Cassin's and *Aethia* auklets, is intermediate. Most *Synthliboramphus* murrelets move away from their colonies, some such as Craveri's Murrelet mostly remaining within their general breeding range, but distances moved by all species tend to be short and rather limited, whether they be to offshore continental shelf waters as in the Ancient and Japanese Murrelets, or along the coast as, for example, in Xantus's Murrelet. The remaining four small, planktivorous auklets winter mainly offshore, but normally near or within the limits of their breeding area, except where waters become ice-covered.

Special cases of extreme long distance movement and pattern complexity are exemplified by Dovekies and Thick-billed Murres in the Atlantic Ocean and adjacent seas. Dovekies undertake migratory movements of considerable length. Two principal patterns dominate, one that brings most of the enormous population from north-west Greenland to waters off Newfoundland and south-west to the Scotian Shelf, and a south-westerly movement from the European high Arctic into the north-east Atlantic with some birds eventually reaching south-west Greenland. In the north-west Atlantic, Greenland birds move 3500 km after breeding is over in late August and occupy the Labrador Shelf, Grand Banks and Scotian Shelf from late October right through the winter. Movements are timed to coincide with ice-edges and concentrations of food. They move first into the ice-covered waters of western Baffin Bay where they feed at rich ice-edges, then go south with the East Baffin Current to the juncture of the Davis and Hudson Straits, where there is another rich source of epontic food and a late zooplankton bloom. Movement out of the Hudson Strait region occurs slowly, but the birds reach southern Labrador and Newfoundland from October to December. The Grand Banks are the principal winter quarters, an area where plankton is exceptionally abundant and where blooms of copepods begin as early as February. The birds concentrate at the shelf edges where existing fronts and upwellings result in high-density zooplankton patches. They begin to move north in April, appearing back at their colonies in north-west Greenland in mid-May. This 7000 km round trip is made up of a series of journeys from one food-rich water area to another, as are the movements displayed by the European Arctic Dovekies in the north-east Atlantic.

Movements of Thick-billed Murres in the Atlantic are even more complex. Like Dovekies, there are two main pathways from northern breeding locations to wintering areas, both associated with major current flow patterns. In the north-west Atlantic, birds from colonies in the eastern Canadian Arctic and west Greenland move south via the East Baffin and Labrador Currents to eastern Newfoundland, where most birds winter on the Grand Banks, whereas those from the European Arctic move south-west using the East Greenland Current towards south-west Greenland. However, not only do the birds from the different regions arrive at different times and spend different amounts of time in south-west Greenland and Newfoundland waters, but the timing of the appearance of adults and immatures differs. Although there is some overlap, of birds coming from Arctic Canada and Greenland many more young birds than adults arrive in south Labrador and east Newfoundland in September and October, whereas adults normally appear in November. The numbers of birds from the Barents Sea region (Bear Island, Murmansk coast, Novaya Zemlya) and from other east Atlantic colonies (Spitsbergen, Iceland, east Greenland) that reach south-west Greenland are unknown, but the majority of European murres are believed to winter in the east Atlantic. At least a few disperse as far as Greenland, some of these moving still farther south-west to east Newfoundland waters where recoveries of birds ringed in Spitsbergen and east Greenland show that at least some east Atlantic murres winter on the Eastern Grand Bank. Thick-billed Murres initiate their northern and north-eastern movements away from the Grand Banks and south-west Greenland in March. Only a long-term ringing programme at a representative number of the major North Atlantic colonies will permit any possibility of clarifying this complex set of population movements and migratory patterns.

Movements elsewhere are usually less complex, even where information is incomplete. For example, in the North Pacific, Thick-billed Murres and several other northern auks, for instance the *Aethia* auklets, remain relatively close to their breeding locations except where ice conditions interfere. Some murres

overwinter in the east Chukchi Sea, north to Cape Thompson and Point Hope, others move out of the north Bering Sea due to ice into the central and south Bering Sea, along with Crested and Least Auklets and other alcid species. Farther south, the degree of migratory movements are variable. Xantus's Murrelets move away from their south California colonies offshore, moving westwards over the shelf area and north as far as southern British Columbia and northern Washington, whereas Craveri's Murrelets remain rather sedentary showing only local, short distance movements north and south of their breeding sites. In contrast are the Pacific puffins, both species wintering far offshore, with the Tufted Puffin moving farther, often off the continental shelf into deep mid-Pacific waters.

The key message derived from any examination of movements of alcids throughout the oceans they inhabit year round is how little is known. Explanations and interpretations presented for the movements of single species or general patterns of movement of Alcidae as a whole in either the Atlantic or Pacific Oceans are little more than best guesses. Considerably more detailed work is required to unravel the complexities of present day movements of existing species, particularly interpopulation differences within the same species, to say nothing about their evolutionary origin and current biological significance.

Relationship with Man

The history of interactions between alcids and humans is a long one. It goes back as far as humans have been a species living and depending upon the sea for at least part of its sustenance. In recent times, man has become enamoured by certain auk species like the puffins, particularly the Atlantic Puffin, because of their exotic appearance, overall beauty, and often "human" antics; their upright posture on land, as they strut to and fro at colonies, displaying many of our own "comic" forms of behaviour ranging from affection to bickering and fighting, has endeared them to many people. The clearest evidence of this lies in the enormous numbers of people that flock to sites where they can see puffins and other auks at their colonies, and by the legislation enacted to conserve and protect them from harmful human activities. But this attitude towards Alcidae is new, a reflection of technological man and his move away from subsistence and recreational hunting in many parts of the developed world, although not everywhere for example in Canada, Greenland, the Faeroes, Iceland, Norway and Russia. In the recent past, however, the relationship was exclusively man the predator and auks the prey, a story of extreme human exploitation and destruction.

Alcids have been hunted by humans for food, feathers and oil for thousands of years. The presence of auk bones of many species, including the Dovekie, Great Auk, murres, auklets and puffins, in archeological middens throughout the family's range from eastern Asia through western and eastern North America to Scotland, Norway and Russia dating back to at least 3000 BC attests to the widespread use of Alcidae. The magnitude of early human exploitation and its impact on auk colonies and populations are unknown, but traditional hunting was probably only of local importance, given the small sizes of human populations and their limited distribution and hunting methods. Utilization by early coastal peoples was likely as a secondary food source, restricted mainly to the collection of birds and their eggs at colonies during summer, with fish and marine mammals comprising the principal part of their diet year round. But by the turn of the nineteenth century, the extent of the pressure from humans increased dramatically and impacts became obvious. Human populations expanded rapidly in size and range, particularly along accessible coastlines in north-western Europe, southern Britain, eastern Canada and the north-eastern USA, causing the extinction of many colonies.

Continued human population growth from the mid-nineteenth to early twentieth centuries, combined with the technological development of more efficient fire-arms and boats, resulted in still further pressure on auks. In temperate regions where people were concentrated, the demand for food and land was high, and many coastal island colonies were destroyed by habitat alteration through the construction of buildings, introductions of alien predators or domestic animals, or direct overexploitation for food. For example, Common Murres and Atlantic Puffins were once numerous and widespread in Atlantic Canada and New England (north-east USA), but lengthy persecution by egging, shooting and netting during the second half of the nineteenth century brought both species close to extinction throughout the region by the early 1900's. Part of this massive reduction came from commercial egging enterprises that were initiated in the mid-nineteenth century at murre colonies along the North Shore of the Gulf of St Lawrence and Labrador, to supply southern markets in Halifax and Boston with exotic foods. About 500,000-750,000 Common Murre eggs were collected each year by schooner fleets until the murre populations collapsed in the late 1880's. Puffin populations in the region also declined during the same period of time, but mainly from excessive hunting of breeding birds and destruction of the nesting habitat, activities that continued through to the 1920's even after widespread local extinctions had taken place. Similar declines of the large auks occurred in Western Europe through the same period. In Britain and Ireland, major decreases took place from the late eighteenth century to early in the present century, especially on accessible islands along the west coasts. Populations in northern Spain and France, the North and Baltic Seas, and parts of the Barents Sea were also severely reduced by human activity, particularly egging, hunting and netting during the breeding season.

Generally, alcids breeding in large, dense colonies have been vulnerable to human persecution wherever they have been accessible. Even colonies in remote and relatively inaccessible regions such as the Arctic became targets as northern exploration exploded through the nineteenth century. This meant the removal of "buffer" refuges that partially offset the destruction taking place farther south of certain species like the murres. Once the resources of the immense Arctic populations became exposed, heavy human exploitation quickly followed by sailors and whalers looking for sources of fresh meat, and commercial developers searching for new products to sell.

Large-scale alcid harvesting operations have been common in the Atlantic and Pacific Oceans in the past and this century. For example, Thick-billed Murres in the Atlantic have been intensively hunted at their colonies and wintering areas for at least 130 years. In Greenland, where records of population changes are best known, heavy shooting at west coast colonies since the 1880's has resulted in drastic declines of the species. Many colonies have been extirpated, and those that have survived are much reduced in size. Since 1930, the murre population has fallen by at least 35-50% to a current level (1990) of about 535,000 breeding birds. This dramatic decline has been caused by the combined impact of: summer and winter hunting in Greenland, with an annual kill estimated at 200,000 birds in the late 1940's, and 300,000-400,000 birds in 1988-89; massive drownings in offshore salmon gill-nets, with 250,000-500,000 birds perishing annually from the 1960's to 1976, when the fishery was closed; and additional large-scale unregulated winter hunting in Newfoundland and Labrador. Birds shot in Greenland are sold at local settlements, and until recently were also sent to freezer processing plants for export to Danish markets.

Other Atlantic entrepreneurial developments have also taken place. A project initiated in 1927 to collect Thick-billed Murre eggs and young at the large colony on Novaya Zemlya in the eastern Barents Sea was so intensive that it caused the murre population to decrease from 1,600,000 birds in 1933 to only 290,000 in 1948, a decline of about 82% over 21 years, from which the birds have yet to recover. Similar unregulated actions have occurred where large concentrations of breeding auks existed. In the Faeroe Islands, overharvesting of Common Murres resulted in population declines from the late 1950's to the 1980's, aggravated by shortages in the birds' food supply due to commercial fishing. However, one of the most serious recent assaults on alcids anywhere has been the winter hunt of murres in Newfoundland-Labrador, where traditional low-volume subsistence hunting of the 1940's has changed to a massive "black-market" and recreational sport hunt without bag limits: birds are sold illegally, and residents of the province can legally shoot as many

Common Murres are social birds at all times of the year and they form breeding colonies that vary in size from small to huge, with densities that can reach 20 pairs/m². It would seem that the birds prefer such densely packed areas to less crowded ones, and close physical contact is widely tolerated among neighbouring pairs. The colonies are situated on rocky coasts with high, perpendicular cliffs and on the tops of isolated stacks, though more low-lying coasts may be used, provided they are remote, undisturbed and free from predators. The birds lay on broad or narrow ledges, less frequently in rock crevices or caves, or under boulders. There is no nest; the single large egg, very variable in ground colour and markings, is laid directly on the bare rock, where its remarkably pyriform shape helps to stop it rolling over the edge. Losses are mainly due to eggs falling off ledges and also to predation. Gulls, ravens and crows frequently act more as scavengers than as predators, but when the whole colony is disturbed or the adult bird is not in attendance, there is ample opportunity for them to take eggs and chicks.

murres as they wish between 1st September and 31st March. This has resulted in annual kill tolls of 500,000-1,000,000 birds from the 1960's to the present time (1995/96) involving mostly Thick-billed Murres from the eastern Canadian Arctic, West Greenland, Spitsbergen and Iceland. The expansion of the Newfoundland hunt was caused by economic growth in the province and the introduction of high-powered fire-arms and speedboats, combined with the relocation of most of the human population from rural to urban situations, resulting in a market for selling birds to people who no longer have easy access to the birds. Regulations have recently been established (1994/95), but these new rules are virtually unenforceable owing to the size and remoteness of coastal Newfoundland-Labrador. This hunt is almost certainly responsible for much of the 30% decline of Thick-billed Murres observed in eastern Canada between the 1950's and early 1980's, as well as possibly being a major contributor to murre declines in west Greenland and those reported for other alcid species that are mistakenly shot for murres, namely Razorbills and Atlantic Puffins. The killing of murres in the north-west Atlantic is one of the most pressing seabird conservation issues in the Northern Hemisphere today.

Human exploitation of auks in the Pacific Ocean came later, but has been just as severe. The entire Bering Sea area and adjacent regions of the North Pacific have suffered serious impact from human activities since the mid-eighteenth century. From this early period of exploration and expansion of human populations to the 1950's, there was uncontrolled and widespread exploitation of alcids and other seabird species, mainly by shooting adults and large-scale collecting of eggs and chicks at colonies. However, introductions of alien animals, such as Arctic foxes (*Alopex lagopus*), red foxes (*Vulpes vulpes*), rats (*Rattus norvegicus*), ground squirrels (*Spermophilus undulatus*), domestic livestock and game animals, to seabird islands have had the most drastic consequences on auk populations. Although fox farming in eastern Russia and Alaska was begun in the eighteenth century by Russian fox trappers, it was not until the early 1880's, when the government of the USA leased Alaskan islands for the propagation of foxes, that the industry grew, particularly through the early 1900's in response to the demand for fox furs by the fashion trade. Arctic and red foxes were deliberately released on islands with large and accessible alcid populations which were viewed as inexpensive sources of fox food. Rodents were also introduced as food for the foxes, especially ground squirrels, voles (*Microtus*) and mice (*Mus*), but that only compounded the predation pressure on the alcids. During this period, alien foxes mainly ate seabirds including enormous numbers of alcids estimated at certain island colonies to exceed 40,000 annually. Large breeding colonies of Ancient Murrelets and Cassin's, Crested and Whiskered Auklets were extirpated from the 1900's to the 1930's, with other species like Common Murres and Tufted Puffins also markedly reduced or eliminated. By 1945, foxes had been introduced to over 450 islands from south-east Alaska to Attu Island, at the western end of the Aleutian Islands, at an immense cost to alcid populations through the destruction of hundreds of breeding colonies. Fortunately, the demand for fox furs has declined steadily since the 1930's, and island fox-farming has therefore diminished in Alaska and many parts of eastern Russia. However, many introduced fox populations continue to thrive on former and active auk colonies, and eradication programmes on certain islands are under way or being considered, albeit slowly owing to limits placed on the use of control toxicants and the high costs of fox removal programmes. Alien foxes now remain on only 48 islands in Alaska. In contrast, in the north-west Pacific, where despite very low profits from fox-farming and enormous damage to breeding auks and other seabirds, recommendations for new introductions of Arctic foxes to the Kuril Islands and nearby regions have recently been made. Some sites important for alcids have recently received special protective status, for example Moneron Island and Sakhalin, but removal of introduced predators from such nature reserves remains at the discussion stage.

Predation by introduced mammals has been the principal cause of the reduction or extinction of alcid populations and their island colonies throughout northern regions of the North Pacific. But in more temperate coastal regions of western North America and eastern Asia, damage from introduced domestic livestock (sheep, goats, pigs) and pets (feral cats and dogs) has been as devastating to seabird colonies as that of alien predators. Rats introduced to islands by human visitors have had serious impacts on breeding seabirds almost everywhere. Next to rats are mink (*Mustela vison*) and raccoons (*Procyon lotor*), both of which have historically been introduced to seabird islands, and most recently on the Queen Charlotte Islands, British Columbia, where they pose a major threat to Ancient Murrelets and other auks. South of British Columbia, along both Pacific coasts to Japan in the west and Baja California in the east the impact of human activity on seabird colonies has been longer and more varied than in the northern regions. Problems have ranged from predation by feral dogs and cats in Craveri's and Japanese Murrelets, by rats in the Pigeon Guillemot, Ancient Murrelet, Cassin's and Rhinoceros Auklets and Tufted Puffin, and by other small rodents like voles and deer mice in Xantus's Murrelet, to trampling and erosion of the breeding habitat of subterranean nesters by grazing herbivores such as sheep in Rhinoceros Auklets, and European rabbits (*Oryctolagus cuniculus*) in Rhinoceros Auklets and Tufted Puffins. Feral cats and dogs remain a serious problem on islands in the Sea of Okhotsk, particularly on Sakhalin and in the Kuril Islands.

Direct human exploitation of auks on a commercial scale has also taken place on both sides of the Pacific Ocean. In the north-west, alongside fur-farming enterprises was the development of commercial fisheries during the 1920's and 1930's. One outgrowth of this new industry was the systematic destruction of seabird colonies in areas considered important for the fisheries. Seabirds were regarded as serious competitors for the available fish which led to a programme in the mid-1950's to eradicate cormorants, gulls and alcids breeding in the Sakhalin and Kuril Islands area by egging, shooting, netting and poisoning. The Common Murre was targeted and an uncontrolled programme launched to take 200,000 eggs, 420 t of meat, and 2100 m^2 of murre-skins for commercial use. Murre numbers at the largest colony on Tyulenii Island rapidly declined, from about 650,000 birds when the programme began to about 140,000 by 1960 and 100,000 in 1976. Although this destructive initiative has ceased and certain island and water areas have received protective status under new legislation, significant egg-collecting and shooting of birds at colonies continues within most locations where commercial fisheries occur and law enforcement is absent.

In the north-east Pacific, large-scale commercial egg-collecting of alcids is known only from the Farallon Islands, California, dating back to the 1850's. Excessive collecting of Common Murre eggs at Farallon colonies caused the murre population to decrease from about 400,000 birds in 1850 to only a few hundred by the 1920's. Some recovery took place over the next 25-30 years with numbers reaching 6000 birds in 1950, but population growth was slow, owing to additional pressure from introduced predators. Once these aliens were removed, the murres increased to over 80,000 by 1982, but the population has fallen once again, apparently due to high mortality in the gill-nets of newly established commercial fisheries.

Perhaps the true nature of Alcidae and human interactions is best exemplified by the history of the extinct Great Auk, the only alcid species exterminated in recent times. This large and flightless auk, the "penguin" of the Northern Hemisphere, and the first species to be called Penguin, had a widespread distribution in boreal and low Arctic waters of the North Atlantic, probably breeding in large numbers on coastal islands free of predators within suitable distance of an adequate supply of fish. While it had become extremely well adapted for underwater swimming and diving with its small flipper-like wings and streamlined body, those same features made for a clumsy and defenceless existence when on land, to which it had to return to for egg-laying and incubation. Upon the arrival of man the predator in coastal regions, safe sites for breeding diminished as colonies close to land were exploited and probably extirpated in a short time after their discovery; the kitchen middens of ancient peoples reveal the efficiency of these early bird hunters.

The Ancient Murrelet, a small alcid of the temperate north Pacific, breeds on islands that are often densely vegetated. Nocturnal at the breeding colony, it nests chiefly in burrows excavated in the soil, favouring areas with dense growth of matted grass, but also in natural cavities under trees and rocks, usually on slopes within 300 m of the sea. The two eggs are laid at night at the end of the short burrow in a scrape lined with grass, leaves and twigs. Both sexes incubate, nearly always in complete darkness, for periods lasting some 72 hours, the longest incubation shift known among alcids. As incubation begins after the laying of the second egg, hatching is synchronous. The highly precocial newly hatched chicks remain in the nest unfed for 1-3 days until they depart seawards at night, usually escorted by both parents. The family group then swims away from the colony, often covering a considerable distance in a short time. The parents care for and feed the young until they are fully grown at 4-5 weeks. Nesting success at undisturbed sites is high, with most losses attributable to desertion of nests prior to the start of incubation rather than to predation.

[*Synthliboramphus antiquus*, Chilbal Island, Yellow Sea, Korea. Photo: Moo-Boo Yoon]

By historical times, most of the easily accessible Great Auk colonies were gone, and remnant populations were probably restricted to remote and inaccessible locations for breeding, mainly predator-free offshore islands associated with biologically productive water systems such as those in eastern Canada and Iceland. As man's sea-faring abilities increased, so did the vulnerability of surviving Great Auk colonies to further human predation. By the early seventeenth century, the last large breeding site on Funk Island, a small rocky islet 60 km off the east coast of Newfoundland, was a regular stop-off site for sailors, fishermen and merchants for restocking their fresh meat supply after an arduous trans-Atlantic voyage from the Old World. Before long, commercial ventures began at the Funk Island colony, first as a source for eggs, meat and oil to sell, and then feathers for the lucrative mattress trade. Teams of men went ashore each summer to corral and boil Great Auks, a practice that continued for more than 100 years before the species became exterminated on Funk Island by 1800. In order to have withstood such a lengthy and continuous persecution, bird numbers must have been enormous on the island, and indeed have been estimated to have been at least 100,000 pairs, based upon bird size and island area. At that time, the status of the Great Auk became known to the scientific community as a rare species on the verge of extinction, prompting a rush by collectors on behalf of science museums and private individuals to obtain specimens before it was too late. This activity sealed the fate of the Great Auk, and the last known breeding pair was collected for a museum from Eldey, a small island off Iceland, on 2nd June 1844.

Has anything been learned from the Great Auk experience? Over 150 years have passed since the last pair were killed for their skins at Eldey, but human attitudes towards wildlife in general, and threatened species in particular, seem largely unchanged. In rural areas and developing countries, the hunting culture remains intact, believing that all living things on earth are mere resources for the use and benefit of mankind. In the developed world, little conservation concern and action is expressed until a species is endangered globally. The skills of early identification of species with problems, factors responsible, and conservation actions necessary to safeguard the population before it becomes threatened or endangered defines today's conservation requirement. Are we any better than the three Icelandic fishermen who caught and strangled the two Great Auks and sold their dead "booty" to a museum dealer in 1844? As we look around and see the relentless destruction of marine ecosystems in all the oceans of the world through human overexploitation and pollution, the answer becomes obvious. No, we still have a long way to go in our own development if we expect to reverse the "extinction inevitable" principle so deeply engrained in the make-up of *Homo sapiens* towards both itself and the wealth of other living things in the biosphere.

However, the loss of the Great Auk did consolidate public opinion in Britain after the 1850's. Once it was realized that this remarkable bird was gone for ever, conservationists of the day were able to lobby for protection of other threatened seabird species like the Northern Gannet (*Sula bassana*) and Southern Hemisphere penguins, both of which were being overexploited for their oils. In 1869 the British Seabird Protection Act was enacted, the earliest piece of legislation passed to protect seabirds anywhere in the world. It set a benchmark for other nations to follow and emulate. But it took another 40 years of brutal persecution of most marine species and the conspicuous disappearance of many populations of cormorants, gulls, terns and auks to move governments of other countries. Since the turn of this century, attempts to curb the human assault on auks have been many. Protective legislation to control and limit human activity believed harmful to alcid populations now exists for most regions of the North Atlantic, North Pacific and Arctic Oceans. However, effective observation of these laws is spotty and mainly limited to Britain, Ireland, Canada (except Newfoundland-Labrador), the USA, Mexico and Japan. Some countries provide special protection to certain species when problems arise (Faeroe Islands, Iceland, Norway) or enact legislation and regulations that can not be enforced (Canada, Denmark, Greenland, Norway, Russia, Spitsbergen). The conservation task is formidable and solutions few.

In eastern North America the plight of colonial alcids, and seabirds generally, was extremely serious with numerous species close to extinction by the early 1900's. As a consequence of this, a pioneering international treaty, the Migratory Birds Convention, was signed between Canada and the USA in 1916, prohibiting the killing of almost all migratory birds and their eggs in most regions in North America including coastal waters of the three oceans bounding the two countries. This initiative was negotiated because of public pressure, spearheaded by a small group of concerned scientists, that demanded the enactment of the treaty's primary objective of "saving from indiscriminate slaughter and ensuring the preservation of such migratory birds as are either useful to man or are harmless". Thus, an international system of uniform protection over a vast geographical region was established, the first of its kind ever. However, seabirds and some other species could still be hunted by native peoples in certain regions of Canada, a provision that was expanded to include the legal hunting of Common and Thick-billed Murres (between 1st September and 31st March) by all residents of Newfoundland-Labrador soon after the province had joined Canada in 1949. But overall, this major North American conservation accomplishment, combined with the earlier British legislation to protect seabird colonies from disturbance, and regulations prohibiting the hunting of all alcid species in Britain and Ireland throughout the year, provided a solid base for the recovery of many alcid species in the North Atlantic and eastern Pacific. Most auk populations did respond positively to protection and showed some growth during the next few decades.

However, human exploitation of auks continues today at a high level in Russia, Norway, Spitsbergen, Bear Island, the Faeroes, Iceland and Greenland, involving the taking of eggs and killing of adults and young by shooting, snaring and netting, and winter hunting of murres in Newfoundland-Labrador. But certain conservation measures have been put in place recently even where alcids are exploited. For example, in Norway, where all auk species may be hunted from 21st August to 1st March, the dramatic decline of murres and Razorbills prompted the government in 1979 to ban hunting them except in Spitsbergen and Bear Island. In the Faeroes, a law limiting the overexploitation of Common Murres was enacted in 1980, protecting the birds from eggers and hunters from 1st June to 15th August, owing to observed declines in the murre population. Some areas have regulations to protect alcid populations, but enforcement is difficult or impossible. For example, in Greenland, regulations to protect seabirds were first enacted by the Greenland Provincial Council in 1977 and later revised by the Assembly of the Greenland Home Rule Authority in 1988. But hunting restrictions on Thick-billed Murres, the most threatened alcid in Greenland, remained legal outside the breeding season with little likelihood of enforcing the summer ban or winter quotas, and subsequently conservation rules were relaxed (1989-1992) causing an expanded hunt and further reduction of the murre population. Similar situations exist throughout remote regions of eastern Russia where regulations to protect alcids have been only recently established and means of enforcement are absent. In Atlantic Canada, the previously unregulated winter hunt of murres now has rules and regulations, put in place in 1994/95, but it remains to be seen if they can be enforced or have a positive effect on the massive and unsustainable annual kill of 500,000-1,000,000 birds that has taken place in the past.

The significance of other man-induced mortality of auks is also seriously high. Commercial fishing activities have expanded tremendously this century, becoming so widespread and highly developed in capture technology that overfishing and the subsequent collapse of exploited fish populations are commonplace. The impacts on alcids have been extreme and in two forms. Massive commercial gill-net fisheries in the Atlantic and Pacific have caught and drowned millions of auks since the 1960's. The coastal gill-net fishery in California, for example, killed at least 70,000 to 75,000 Common Murres between 1980 and 1986, the principal cause of the 52% decline of the breeding population in central California recorded during that period, one of dramatic increase in fishing effort in the region; significant numbers of other alcid species also drowned including Pigeon Guillemots

The Atlantic Puffin, a highly social species, breeds on grassy slopes along rocky coasts in the North Atlantic, and it forms colonies which are sometimes large and densely packed. Puffins nest in burrows 1-2 m long that they excavate themselves, using both the feet and the bill; the feet serve to dig at ground level and the bill higher up. Alternatively, they may take over an already made burrow from another puffin, a rabbit or a shearwater. In either case burrows are reused in subsequent seasons, the males spending more time on their defence and maintenance than the females. The prime, most successful burrows are those in seaward-facing slopes that are too steep for most predators to reach and where landing sites are nearby so that gulls have less chance of snatching food from adults returning to the burrow to feed the young. The single mainly white egg is laid at the end of the burrow and incubated by both adults, often for spells of more than 30 hours. They feed the chicks and care for them until they finally abandon them in their last days as nestlings. Driven by hunger to leave their burrows, most young fly or walk down to the sea at night and begin to fend for themselves unaccompanied.

and Marbled Murrelets. Estimates of losses of auks in other coastal and high sea gill-net fisheries in the North Pacific suggest high kill tolls wherever the birds and fisheries co-exist, and local populations in many regions are vulnerable, particularly those of Common Murres and Marbled and Japanese Murrelets. Incidental kills of auks in Atlantic fisheries are equally high. The worst recorded case was the Danish salmon gill-net fishery in west Greenland that killed at least 500,000 Thick-billed Murres each year from 1968 to 1975, after which the fishery was closed by regulation. Mortality by accidental drowning in fishing gear occurs where gill-net fisheries occur, inshore and offshore, and such activities are widespread throughout the range of Alcidae involving most member species.

However, direct competition for the same species of fish is perhaps potentially even more lethal to alcid populations. Originally, commercial fisheries were directed at the larger fish species, like cod and herring. But by the 1960's, as commercial stocks were depleted, fishing fleets diversified and redirected their attention to the smaller species, such as capelin, sandeels, herring and sprat, pelagic species often lower in the food chain and central to food webs, such as capelin in both the North Atlantic and Pacific Oceans. These small fish are critical to alcids, and their removal or reduction by human fisheries can have catastrophic consequences for most auk species. Collapses of these small pelagic fish populations have occurred in low Arctic and boreal waters in the Atlantic and Pacific, and overfishing has played a role in most. In many cases, these collapses are accompanied by reproductive failure in colonial seabirds, particularly the auks. The best examples are from the North Atlantic, where fisheries in west-central Norway, the Barents Sea and Newfoundland have had major impacts on alcid populations. In Norway, the collapse of the herring stock in the late 1960's has caused almost total breeding failure of Atlantic Puffins since 1969 with virtually all young produced starving to death before they could fledge, followed by a consequent major decline in the breeding population. Similar food shortages and high chick mortality have been recorded at Atlantic Puffin colonies in east Newfoundland since 1972, when an international commercial capelin fishery began. This fishery underwent a huge expansion until it collapsed for the first time in 1978, reopened in 1982 and then closed again in 1992 when almost no capelin appeared inshore to spawn. Not unexpectedly, the North American Atlantic Puffin breeding population, which is centred in Newfoundland, has decreased by about 30% since 1972. Events in the Barents Sea have been equally catastrophic. On Bear Island, more than 280,000 adult Common Murres, over 60% of the total breeding population, died from food shortages during a single winter (1986/87) due to a collapse of capelin. Fisheries aimed towards these small pelagic "keystone" fish species pose serious threats to Alcidae, perhaps comprising the single most important factor influencing the future welfare of fish-eating auks.

Many auks have also been destroyed by oil pollution, particularly during the past 50 years. The global transportation of oil has resulted in thousands of accidental spills killing millions of marine birds. Auks are particularly vulnerable to oil fouling owing to the unusually large amount of time they spend on or in the water. The large tanker spills in coastal boreal waters have caused the greatest known mortality of alcids and other seabirds. For example, at least 250,000 birds were estimated to have been killed by the 1989 Exxon Valdez oil spill in Prince William Sound, Alaska (see Volume 1, page 572), of which 74% were murres, the highest level of alcid mortality ever reported from a single acute oil spill. The populations of other auks, the Pigeon Guillemot and Marbled Murrelet, were also seriously affected with projections of 50-100 years before recovery of the alcid breeding community. But chronic oil pollution, the small spills from transfer operations, bilge pumping and tank cleaning at sea, probably causes greater mortality of birds overall, as evidenced by the regular beaching of dead oiled birds along coastlines associated with oil tanker traffic, for instance in Belgium, Britain, the Netherlands and Norway, as well as Newfoundland, Nova Scotia, British Columbia, Washington and California.

Apart from direct mortality caused by external oiling on plumage, there are also many sublethal toxic effects of ingested petroleum oils including impaired breeding performance with high embryonic mortality, in addition to developmental and osmoregulatory problems, and haemolytic anaemia. Overall, oil-related mortality has adversely affected alcid populations regionally such as Common Murres, Razorbills and Atlantic Puffins in the North Atlantic and Common Murres in the north-east Pacific, particularly in winter. Species most at risk are those with small total populations that occupy restricted areas like Xantus's, Craveri's and Japanese Murrelets. Although long-term effects of oiling on auk populations are difficult to determine, heavy mortality can be expected to continue in the future in relation to increased tanker traffic and further deep water drilling offshore, often in waters important for wintering alcids and where the likelihood of accidents is high, for instance Hibernia on the Newfoundland Grand Banks and developments in the Sea of Okhotsk, off Sakhalin.

Concentrations of toxic chemicals, essentially chlorinated hydrocarbons and heavy metals, in alcid species are relatively low. Advances in pollution control since the early 1970's, especially on the uses and discharges of persistent organochlorine pesticides and polychlorinated biphenels (PCB's), has resulted in a gradual decline of these pollutants in the marine environment. Residue levels are generally highest in birds associated with industrialized areas such as the Baltic and Irish Seas, the Gulf of St Lawrence and the Southern California Bight. However, no population declines observed in alcids can be attributed directly to toxic chemical poisoning. Despite this fact, sublethal effects of these chemicals on auks are very poorly known, and populations close to sources of industrial and agricultural discharges should be monitored closely.

Overall, human exploitation and disturbance, either directly or indirectly, remain the most important threats to alcid populations in the Pacific, Atlantic and Arctic Oceans and adjacent seas. First and foremost is the continued uncontrolled destruction of alcid populations by egging and hunting in the north-west Pacific, largely by the east Russian fishing fleets, and by summer and winter hunting of Thick-billed and Common Murres, Razorbills and Atlantic Puffins in the North Atlantic,

The Thick-billed Murre accepts narrower cliff ledges for its nest-site than does the Common Murre (Uria aalge). *The single large egg is laid on the bare rock. Very variable in colour, the egg is markedly pyriform in shape, which helps to prevent it from rolling over the edge. A bird preparing to incubate will settle in a nearly upright position over the egg with its back to the sea, its breast pushed up against the cliff face, and the egg resting on the tarsi. The chick is fed and cared for by both parents until fledging, when it jumps off the ledge and glides in a hazardous journey down to the sea, closely followed by one of the parents. Chick and parent join up again on the sea through mutual calling, and then swim out to sea together.*

[*Uria lomvia arra*, St Paul, Pribilof Islands, Alaska, USA. Photo: William M. Smithey/Planet Earth]

A fairly common small dark North American species, Cassin's Auklet breeds in dense communities of roughly 500-1,000,000 birds. Strictly nocturnal at its colony, its nest-site is in a crevice or cave, or in a burrow excavated in soft soil by both adults. Only one egg is laid, which both partners incubate, relieving each other every 24 hours. The semi-precocial chick is fed by both parents only at night until, after about 43 days, it departs for the sea, alone and usually at night.

particularly in west Greenland and Atlantic Canada (Newfoundland and Labrador), but also in the Faeroes and Iceland. Disturbance and predation from introduced alien animals (foxes, small rodents, livestock) at colonies continues to be a dominant limiting factor on some alcid populations, particularly in the North Pacific. However, the single most potentially damaging activity to Alcidae, in both the short and long terms, is commercial fishing. The depletion of small pelagic fish populations, essential to many auk species for reproduction and survival, combined with direct mortality from entanglement and drowning in fishing gear, pose an enormous threat to alcid populations throughout their range, a pressure that can only be expected to increase as the demand for human food escalates over time. Oil spills, small and large, and industrial pollutant discharges continue to contaminate marine systems and their living occupants including alcids. Exposure to these toxic pollutants will likely remain high or increase, as petroleum developments and transport expand with human population growth, as will run-off of chemicals from agricultural activity and industrial effluents. Ultimately, the oceans are the final repository for most of these persistent compounds. If such human activities are allowed to continue or increase, the future of Alcidae can be considered very grave indeed and man's relationship with the family no better than that with the Great Auk 150 years ago.

Status and Conservation

Alcidae has a widespread distribution in the Northern Hemisphere largely coinciding with human populations. Sharing ecological roles as top trophic feeders, auks and people naturally came together in search of a common food source, fish, sometimes in direct competition, but more often perhaps as species co-existing in a marine-based system. The correspondence of both populations in food-rich areas, whether as early human colonizers of Arctic lands or more recently in low Arctic and boreal to cool subtropical water regions, seems self-evident. Places of high biological productivity and activity are not distributed at random, but are concentrated in space and time, and it is that feature of marine waters that doubtlessly brought man and bird together in search for food. Historically, humans occupying marine ecosystems focused on fish as their principal prey, less often on marine mammals except for certain northern peoples. However, large aggregations of seabirds at specific locations and times, whether at sea or on land, offered a substantial supplementary food source to exploit. As a consequence, humans have eaten colonial auks and their eggs for thousands of years. The historical relationship was man as predator, utilizing auks principally for food, but also for fish-bait, with fat to use in oil lamps, and feathers for insulation in clothing and decoration. The tendency of human populations to expand in size and range more recently, within the last 500 years, has resulted in a switch of man from a casual local predator to a diligent destroyer by direct overexploitation for food, alteration and destruction of marine and terrestrial habitats vital to Alcidae, and physical displacement from coastal islands formerly used by the birds for breeding. Man the low-volume auk-predator of historical times is now man the potential exterminator of the Alcidae, directly or indirectly, through human activities in coastal and offshore marine waters of the northern oceans.

Virtually all extant alcid species have undergone widespread decreases in population size and range during the first half of the present century, reductions that began during the eighteenth and nineteenth centuries. Some of these declines continue today. The fate of the recently extinct Great Auk (see Relationship with Man) should serve as a warning to all of how rapid and final the disappearance of a species can be. Presently, there are four species at serious risk: one, the Japanese Murrelet, is globally threatened, with no more than 6000 breeding birds remaining; and three are classed as near-threatened species, the Marbled, Xantus's and Craveri's Murrelets, the latter two with populations of under 10,000 individuals, and both very likely soon to be reclassified as globally threatened. Of equal concern is the increasing vulnerability of several other species including the Razorbill, Black Guillemot, Ancient Murrelet and Whiskered Auklet, all with relatively small populations and in various states of decline over their world ranges. In the short term, the prognosis is far from encouraging as, where sufficient information is available, almost all species indicate declining numbers with only certain regional or local populations in equilibrium or showing slight increases. The family is very vulnerable to man-induced perturbations, either directly or indirectly, clearly exemplified by the recent sta-

tus of its present 22 member species: 12 species (54·5%) are known to be decreasing in numbers, including the four species (18%) that are globally threatened or near-threatened; nine species (41%) vary between stable to decreasing through their range; and only one species (4·5%), the Dovekie, is believed to be relatively stable at present.

That widespread decreases have occurred in population sizes of most auk species should come as no surprise. Top trophic feeders in a food chain are always vulnerable to environmental change and disturbance. In marine ecosystems, seabirds, marine mammals, and humans occupy this position. All three groups share certain features that endanger them: they are long-lived with high adult survivorship, reach sexual maturity slowly, and have low reproductive rates, often rearing only a single offspring annually. The consequences of these demographic characteristics is that recovery from environmental disturbances is slow and that increases in adult mortality have a much greater impact on the population than it does on a species with a high reproductive rate and high adult mortality. For example, a species with high fecundity and a short lifespan, such as a small songbird, may be able to recover from a 50% decrease in population within one or two years, whereas recovery of an alcid species may require 20 years. Thus, high longevity associated with low productivity places a species at considerable risk, features shown by most seabirds.

Like many other marine birds, alcids are especially vulnerable to factors that reduce their numbers, as most auk species have single-egg clutches, breed for the first time at 3-5 years, and display low juvenile survivorship with only some 30% surviving to breed, and a correspondingly high adult survival rate of about 90%. In addition, they tend to have, on the one hand, specialized diets, usually with just 1-2 prey species predominating, and, on the other, mostly clumped patterns of distribution throughout the year, with a high proportion of the total breeding population at only a small number of colonies and the concentration of wintering birds at only a few oceanic areas; together all these factors combine to make most auk species particularly vulnerable to human activities.

Specialists like alcids live a precarious life at the best of times, and, although they long ago adapted to natural variations in their marine environment, they do not adjust easily to changes brought about by man-induced factors, such as depletion of important prey by overfishing or by an oiling incident. The consequences of activities such as these can be severe and rapid. Perhaps the most dramatic example, the collapse of the capelin population in the Barents Sea in 1986, believed to have been caused by overfishing, resulted in the loss at Bear Island of over 400,000 Common Murres (more than 80% of the breeding population) during the winter of 1986/87 owing to food shortages, as well as causing declines of murres and other auk species at colonies in northern Norway. Results can be equally catastrophic when human disturbance from more than one source occurs simultaneously with natural negative events. In California, mortality of Common Murres from oil pollution and drowning in gill-nets combined with prey shortages, partially due to the Southern Oscillation of El Niño (see Volume 1, page 341) in the early 1980's, resulted in a 47% decrease of the murre population on the Farallon Islands. Not only can alcid populations decrease significantly over short periods of time due to human activity, but the impact of such losses can have widespread implications for distant breeding populations. For example, the collapse of the capelin population on the Grand Banks of Newfoundland in 1992 from excessive commercial fishing over the previous 20 years is not only adversely affecting auk populations that breed in the area, but also those species that winter there in large numbers from breeding colonies as far away as the eastern Canadian high Arctic, west and east Greenland, and even Iceland and Spitsbergen. Consequences of present day human disturbance to marine systems can be severe to alcid species.

In the Atlantic, all alcid species except the Dovekie declined during the first half of this century, reductions that began over much of their range by at least the middle of the nineteenth century. Information on the Dovekie is too sketchy to determine what changes in population size and status have occurred for the species as a whole, except for the localized declines known to have taken place this century in Iceland and south-western Greenland. The general impression derived from recent studies at certain colonies in west Greenland and Spitsbergen since the early 1970's suggest a relatively stable population in those regions. Declines have continued to the present time, however, for the Common Murre, Razorbill and Atlantic Puffin, especially in the southern parts of their ranges, and for Thick-billed Murre in the north-west Atlantic. Changes in Common Murre and Razorbill populations have been similar overall, decreases over much of their range at first followed by reductions mainly in southern regions, with numbers stabilizing or showing slight increases at some colonies through the late 1960's and 1970's, and decreases or stable populations thereafter. Large declines of Thick-billed Murres have occurred in many Atlantic locations including the eastern Canadian Arctic since at least the mid-1950's and west Greenland and Novaya Zemlya from the 1920's and 1930's to the present. Atlantic Puffins declined through most of their range until the early 1970's, after which numbers stabilized or increased slightly to the mid-1980's when declines, some marked, began again, continuing now in most regions. The scattered breeding distribution of the Black Guillemot makes it more difficult to examine, but numbers appear to be decreasing in certain northern boreal water parts of its range and remaining relatively stable in the south, the reverse pattern to that shown by Common Murre and Razorbill; nothing is known of status changes of Black Guillemots in Arctic regions.

Causes of the declines are rather straightforward. Human persecution by direct exploitation early on, through egging and hunting, followed by oil contamination and heavy mortality from commercial fisheries, first by large-scale drowning in gill-nets as in Thick-billed Murres in west Greenland, and then by food shortages caused by overexploitation of small pelagic fish as in the Common Murre, Razorbill and Atlantic Puffin. Human predation remains a significant contributor to certain auk declines in eastern Canada, Greenland, Iceland, the Faeroes and parts of Norway and western Russia, the most notable of which is Thick-billed Murre in the north-west Atlantic from largely unregulated hunting in Greenland and Atlantic Canada (see Relationship with Man). Alien predators such as rats and mink have had a significant impact on certain populations, especially in southern regions on both sides of the Atlantic, as have introductions to breeding islands of domesticated livestock, particularly sheep, goats, pigs and rabbits. Disturbance at major breeding colonies by human visitors has increased dramatically over the last 20 years, even in regions recently believed to be remote and relatively inaccessible such as the Arctic. Demands for access to major alcid colonies are frequent and vary in form: tourist developments, often encouraged and initiated by governments for socio-economic purposes; places for university and government biologists to work and for land-use managers to perform their assignments; and subjects for film-makers and naturalists interested in wild places and adventure seekers to have fun. All these activities place extra stress on already hard-pressed breeding populations of colonial alcids. Moreover, these pressures are likely to increase still further in the future as human populations continue to grow and seek additional outlets for their recreational interests.

In summary, over the last two centuries in the Atlantic and adjacent seas, negative influences of humans in the form of direct human exploitation, habitat disturbance and destruction, introduced predators, mismanaged commercial fisheries and incidental kills in fishing nets, oil pollution and chemical poisoning, have resulted in the extermination of one species, the Great Auk, and marked reductions in population size and range of five of the remaining species comprising the North Atlantic alcid community. Two of the five species presently decreasing in numbers have small populations and should be considered vulnerable to further human disturbance and persecution: the Razorbill and Black Guillemot. The future of the Thick-billed Murre in the north-west Atlantic is also precarious, with a 35-50% reduction in the breeding population of Greenland having taken place since the 1930's, including the extinction of numerous major colonies, and major declines elsewhere on both sides

The heavy-billed, starkly black and white Razorbill breeds in habitats similar to those of the Common Murre (Uria aalge), *often forming mixed colonies with it and with other seabird species. Flexible as to nest-sites, its choice ranges from crevices in large rock and boulder fields, cracks in rocky cliff faces or exposed ledges, though it shows a preference for somewhat more protected and concealed sites than the open ledges used by murres. There is no nest, the single egg being laid in a slight hollow in the bare rock. The semi-precocial chick is covered in short thick down with silky tips, mainly darkish brown above, but much lighter on the head and breast. Cared for and fed by both parents until it fledges, it then departs for the sea, escorted by the adult male which will remain with it for at least three weeks.*

of the Atlantic, notably the eastern Canadian Arctic and the eastern Barents Sea. If unrestricted shooting continues at colonies in west Greenland during the breeding season and during the winter in both south-west Greenland and Newfoundland-Labrador where many of the Greenland birds overwinter, the consequences for the Greenland murre population may be very grave. Overfishing and the subsequent collapse throughout the Atlantic of "keystone" forage species such as capelin and herring, small fish critical as food to all Atlantic auks except the Dovekie, pose the greatest threat to Atlantic Alcidae.

Conditions in the North Pacific are no better, perhaps worse. Alcid populations throughout the North Pacific range have been subjected to a lengthy persecution by humans, even in the remote northern regions believed by most people to have gone largely undisturbed until recent times. Nothing could be farther from the truth. Although most northern islands and sea coasts remained relatively uninhabited compared to areas farther south along both west and east coasts, most islands and their resident seabirds were heavily affected by the introduction of foxes, rats, ground squirrels, other rodents and numerous varieties of domesticated cattle and game animals. Insular fox farming, by far the most destructive human activity in northern regions, began in the mid-eighteenth century, peaked early in the present century and continued as an intensive industry into the 1940's, both in Russia and Alaska. By this time irreparable damage had been done, particularly to colonial breeding auks that had evolved on the hundreds of islands free of mammalian predators and therefore lacking defences against alien predators like foxes when they appeared. On island after island, breeding populations of auklets, puffins and other seabirds disappeared or became drastically reduced because of introduced foxes that were deliberately released on colonies by fur trappers to exploit the auks as fox food. Foxes, combined with other introductions such as rats, squirrels, mink, raccoons and other rodents, devastated auk populations for at least a century and a half. Farther south along both west and east Pacific coasts, human disturbance of alcid colonies came in the form of direct exploitation through egging and hunting for food, feathers and oil, and the introduction of alien rats, domestic livestock and feral pets. The history of human impact on alcids throughout the North Pacific is lengthy and documents severe widespread persecution (see Relationship with Man).

The current status of the offshore fish-feeding auks in the North Pacific, the Common and Thick-billed Murres, Rhinoceros Auklet, Tufted and Horned Puffins, is unsettling. The murres have declined markedly through most of this century, declines that have continued over the last 25 years in much of the Bering Sea area, north-west Pacific and parts of the west coast of the USA with populations in certain regions stable or showing increases, though remaining far below recent historical levels. Information on the Rhinoceros Auklet and puffins is poor, but available data indicate major declines overall in all three species, with some parts of the population of the Horned Puffin and Rhinoceros Auklet stabilizing or increasing, respectively, since the early 1970's. The size and status of the four inshore fish-feeding alcid populations in the North Pacific are more difficult to determine, owing to their more dispersed breeding patterns. Generally, the two resident *Cepphus* guillemots have declined this century, mainly due to introduced predators. The Pigeon Guillemot has undergone marked declines in northern and southern parts of its range, in the Pribilof and Farallon Islands respectively, as has the Spectacled Guillemot at colonies in northern Japan, with a 93% decline between 1963 and 1987, and eastern Russia, with a 53% decline since 1979. The total population of the Spectacled Guillemot numbers less than 75,000 pairs, is concentrated and is declining, which together clearly indicate a ma-

The Japanese Murrelet, an attractive little species, is the rarest of all alcids. It is restricted to five small breeding areas on islands of south-east Japan. With a total population estimated at only some 5000-6000 birds in 1995, it is considered globally threatened and is currently classified as Vulnerable. Biro Island probably holds at least half of the total population. One or two days after hatching, the chicks leave the nest at night with their parents and go to sea where they will feed for the first time.

[*Synthliboramphus wumizusume*, Biro Island, Kyushu, Japan. Photo: Koji Ono]

jor problem probably warranting globally near-threatened status. Disturbance by alien predators, illegal hunting, and oil developments offshore in the Sea of Okhotsk all pose major threats to this species. Both *Brachyramphus* murrelets appear to be experiencing declines. Destruction of old-growth forests from south-east Alaska to California and in the Sea of Okhotsk poses a serious threat to the future of Marbled Murrelet populations. Major declines in bird numbers have already occurred, partly due to continued removal of nesting habitat, but also undoubtedly from the chronic problem of birds drowning in commercial gill-nets, and mortality from oil spills along the entire west coast of North America. Although the status of Kittlitz's Murrelet is uncertain, either stable or decreasing, considerable numbers were killed in the Exxon Valdez oil spill in 1989 which has raised serious concern.

The *Synthliboramphus* murrelets and the auklets occur around the rim of the North Pacific and adjacent seas. Although their general distributions are well known, sizes of populations within many regions are poorly known and they are all difficult to census owing to their nocturnal activity patterns in the case of murrelets and Cassin's Auklet, or subterranean and often inaccessible nest locations in the *Aethia* auklets. The Ancient Murrelet and Cassin's Auklet range widely from northern boreal to cool subtropical waters. Both species were decimated by foxes in the Aleutian Islands and northern Gulf of Alaska during the lengthy fox farming era, and significantly reduced in numbers elsewhere by other alien introductions, notably rats, cats and raccoons, and also by human disturbance. The other three murrelet species, Xantus's, Craveri's and the Japanese, have restricted mostly cool subtropical distributions and are all threatened to near-threatened species. The Japanese Murrelet is probably the rarest alcid in the world with a maximum of 6000 individuals, its numbers reduced by human disturbance and introduced predators this century to its present critical low level and globally threatened status. Xantus's and Craveri's Murrelets also have extremely small and restricted populations that are designated globally near-threatened. Feral cats, rats, deer mice and livestock introductions, combined with other human disturbance at breeding colonies, have been responsible for the decline of both species. Removal of cats and other alien mammals from Xantus's Murrelet colonies in the Channel Islands, California, has had positive results; additional predator eradication programmes are required at other breeding sites in southern California and the outer coast of Baja California for Xantus's, and in the Sea of Cortez for Craveri's.

The Parakeet Auklet and three *Aethia* auklets all breed predominantly in low Arctic and northern boreal waters in the Bering Sea and Sea of Okhotsk, showing only a little overlap with murrelets and Cassin's Auklet. Although they have not been surveyed thoroughly because of deficient census methods, certain trends seem clear. All four species have been seriously affected by introduced mammalian predators and human exploitation and disturbance from the late nineteenth to the middle of the twentieth century. The Whiskered Auklet has the smallest population and most restricted distribution of the *Aethia* auklets, making it highly vulnerable to human activity. Alien rats and foxes at colonies, combined with recent high mortality from oil pollution and fatal attraction to ships' lights suggest the species may be declining in parts of its range. Current trends of Crested and Least Auklets are uncertain: in both species, some populations appear relatively stable while others are decreasing. Crested Auklets underwent drastic reductions throughout their range due to fox farming, and present numbers are only a small fraction of what they were before foxes were introduced. For example, the large colony at Yukon Harbor in the Pribilof Islands fell from a high of 300,000 birds in the early 1900's to 30,000 by the mid-1970's, and only 6000 in the mid-1980's. The removal of foxes from some island colonies in 1985/86 in Alaska has resulted in populations becoming stable or even increasing slightly, but declines continue at other locations due to human disturbance, alien predators and oil pollution. The Least Auklet is the most abundant auklet in the Bering Sea and Sea of Okhotsk, but it too has decreased in numbers in recent times. Qualitative assessments suggest a declining population overall with marked decreases at Pribilof and Aleutian colonies, as well as serious reductions from human disturbance and introduced predators at colonies in the Sea of Okhotsk. The Parakeet Auklet population has also probably undergone a major reduction in size and numbers of colonies since the turn of this century for the same causes. Today, introduced predators, commercial fisheries and marine pollution, through both oiling and the ingestion of plastics, pose serious threats, as they do to the other auklets and murrelets.

Overall, human exploitation and disturbance at alcid breeding colonies in the North Pacific during the last 150 years or

more have had severe and disastrous consequences for the birds. Hundreds, if not thousands, of auk colonies have been destroyed and even greater numbers of islands have undergone permanent damage from direct human habitat alteration and occupation, as well as introductions of alien animals. More recent assaults from intensive commercial fisheries, offshore petroleum developments and transport, and widespread removal of old-growth coniferous forests along both Pacific coasts have added to the impact on the auk community. Consequences have been marked. Almost all 18 alcid species are in a state of disequilibrium, with populations either known or suspected to be decreasing in size and range. The Japanese Murrelet is classed as Vulnerable, with extinction in the near future a distinct possibility. Three other species, the Marbled, Xantus's and Craveri's Murrelets, are globally near-threatened, and an additional three should be so designated, namely the Spectacled Guillemot, Kittlitz's Murrelet and the Whiskered Auklet. Human disturbance and exploitation, followed by introduced mammalian predators, oil pollution and commercial fisheries, remain the greatest threats to alcid populations in the North Pacific.

To conclude, the future of the 22 species of Alcidae distributed in the North Pacific, North Atlantic and Arctic Oceans must be considered precarious, particularly as human disturbance is likely to be even greater in the future. Direct exploitation of alcids for food, oil and feathers, though now much reduced over the family's world range if compared with the first half of this century, remains significant and at unsustainable levels in eastern Russia and certain parts of the North Atlantic, notably Russia, Norway, the Faeroes, Iceland, Greenland and Canada. The most serious threats to auks come from the indirect effects of other human activity: drowning in fish nets and oiling, when the birds are at sea; and, when they come ashore to breed, alien predators, artificial increases in natural predators, human disturbance and tourism; also, indirectly, by reducing the quality and quantity of their food supply through fishery developments, overfishing, and toxic chemical contamination. The present conservation needs for Alcidae require the total protection of the most important breeding colonies, including the land and adjacent waters, and key feeding areas both inside and outside the breeding season. Sites used for reproduction require protection from the many sources of human disturbance, both direct and indirect. An international system of enforcement must be developed to ensure that regulations are respected and effective in the attainment of management and conservation objectives. But can these conservation goals be attained, and if they can, what general approaches to management and research need to be implemented and followed?

Solutions to these problems are by no means clear. To be effective, a management strategy must comprise a careful co-ordination of effort on a regional, national and international basis, to permit an adequate assessment of threats to be made and solutions developed. Conservation biologists must not limit thoughts to a single colony or species, or even to a small area of ocean, but instead collectively agree to standardize protocol and co-ordinate activities, and to sample entire ranges of individual species and oceans. Only in this way can we expect to succeed in the formulation of a meaningful conservation policy and the identification of processes and actions by which alcid diversity and abundance can be protected and maintained. The overall conservation plan required for auks today must satisfy a suite of general requirements.

First, it is essential to regulate the impact of general and specific environmental stresses on alcids and their marine and terrestrial habitats including: offshore petroleum developments, operations and transport systems; national and international fisheries directed towards forage prey species (fish and invertebrates) important to alcids throughout their annual cycle; and forestry developments and operations targeting critical nesting habitat, such as old-growth forests.

The second requirement is the mitigation and removal of current man-induced disturbances known to be adversely affecting individual species populations with: the cessation of human predation, particularly in eastern Russia, Norway, the Faeroes, Iceland, eastern Canada and Greenland; the eradication of introduced alien predators from important extant alcid colonies and former breeding sites; the elimination and control at key breeding colonies and nesting sites of human disturbance, including habitat alteration and destruction, the presence of domesticated animals, tourism, and other unnecessary human activity; and restrictions and control of commercial fisheries within areas of important colonies.

The third point is to establish programmes to protect, preserve and restore important breeding colonies and marine and terrestrial habitats on regional, national and international levels.

Fourth, it is essential to maintain or establish monitoring systems capable of measuring key population parameters of individual species that will produce statistically meaningful results to determine current status at major colonies, predict changes, and identify cause-and-effect relationships.

Fifth, a global database for Alcidae should be developed, to bring regional and national data sets together to provide a baseline for the assessment of species population changes on a wide range, a system capable of examining whole ranges of species and entire oceans.

And finally, a multinational site classification system should be established to facilitate easy identification of alcid sites (colonies and marine water areas) of national and international importance to be designated "significant" and worthy of protection; this approach will allow international designation to be given to individual sites and force national owners to accept the "special site" status and provide the protection necessary under national laws and international treaties.

In the end, it is critical to remember that successful conservation of auks is dependent upon long-term compliance of conservation policy which can only be attained through education and understanding. Biologists and managers must therefore devise better communication pathways and networks to inform people of conservation needs and explain why wildlife laws and regulations are required. It is essential that both ecological and human factors, and their interactions, are considered in the formulation of policy. This is particularly important in regions where subsistence hunting was, or remains, part of the traditional culture. In these cases, increased education aimed at all age groups, but particularly at children and their parents, is essential to the adjustment of traditional mores and to reinforce alcids and other marine wildlife as part of their culture. This approach may be the best defence for many alcid colonies and habitats. Clearly, conservation goals can only be attained by a combined effort through public education, public pressure, and the enactment of suitable legislation, all of which requires public awareness and support. The management of alcids and other seabirds will remain largely at the ecosystem level: protect the island or mainland site and its nearby waters, and those marine areas known to be important outside the breeding season, and manage them for alcid species and communities. By managing auk populations successfully, we will prevent large-scale destruction of a rich group of marine animals, and contribute to maintaining the health of the world's oceans on which most living things depend.

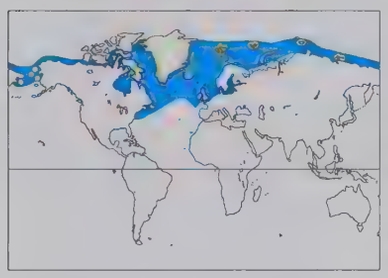
PLATE 59

inches 6

cm 15



Genus *ALLE* Link, 1806

1. Dovekie

Alle alle

French: Mergule nain **German**: Krabbentaucher **Spanish**: Mérgulo Atlántico
Other common names: Little Auk

Taxonomy. *Alca Alle* Linnaeus, 1758, Scotland.
In past, species was commonly placed in monotypic genus *Plautus*, but this name was deemed unavailable, giving way to *Alle*. Normally treated as polytypic, but evidence incomplete and requires further examination; subspecific status of populations breeding Severnaya Zemlya, New Siberian Is and Bering Sea uncertain. Two subspecies normally recognized.
Subspecies and Distribution.
A. a. alle (Linnaeus, 1758) - E Baffin I through Greenland and Iceland to Jan Mayen, Spitsbergen, Bear I and Novaya Zemlya.
A. a. polaris Stenhouse, 1930 - Franz Josef Land, and possibly this race in region from Severnaya Zemlya E to Bering Sea (St Lawrence I, Little Diomede).
Winters mainly in low Arctic waters from Grand Banks of Newfoundland E across N Atlantic to N Norway; also regularly in boreal zone S over Scotian Shelf and Gulf of Maine E to N Scotland and North Sea, rarely farther S.

Descriptive notes. 17-19 cm; 163 g (140-192 g); wingspan 40-48 cm. Rather distinctive small, compact, chubby auk with short, stubby black bill and black iris; glossy black head, neck and upperparts, with browner-toned face and upper breast, contrasting with white underparts; white-streaked scapulars and white-tipped secondaries; legs and feet blackish grey. In winter, chin, throat, upper breast and ear-coverts white. Juvenile resembles summer adult, but generally paler and browner. Races rather similar, based upon size differences only; *polaris* larger overall, including longer bill and wing.
Habitat. Mainly high Arctic, breeding in large colonies on sea coasts, usually in crevices in rock scree of maritime slopes. Mostly pelagic during winter, mainly in low Arctic waters, often associated with edge of pack ice, and in boreal zone; rarely farther S. Winter distribution corresponds with regions of greatest abundance of oceanic zooplankton.
Food and Feeding. Feeds mainly on small invertebrates, especially copepods, amphipods and euphausiids, less frequently decapods and gastropods; also fish larvae. Chick diet mainly comprises planktonic crustaceans, *Calanus* copepods and amphipods; parents deliver c. 5-8 meals/day, each amounting to 3·0-3·8 g. Species is opportunistic feeder, usually foraging within 100 km of colony, often much closer; food transported in gular pouch. Dives normally last 30 seconds or less, probably most to depths of less than 20 m, though rarely to 30 m. Winter diet poorly known, but planktonic crustaceans and other zooplankton are presumably important.
Breeding. Spring arrival at colony is variable, from late Feb to early Mar at Franz Josef Land, early Apr in Spitsbergen, and early May in NW Greenland; laying occurs in late Jun, and fledging complete by end Aug. Forms immense colonies at selected sites in high Arctic, breeding in scree slopes on coastal cliffs; egg often laid on bed of small pebbles lined with fragments of vegetation. 1 egg; incubation averages 29 days (28-31), by both sexes equally, with c. 4 change-overs each day; downy chick blackish brown, with paler belly, c. 21 g, semi-precocial; chick-rearing usually 27-30 days, with care and feeding by both parents; chick apparently becomes independent at fledging, when flies out to sea alone. Breeding success variable, with average of c. 50-52% of eggs laid producing fledglings; most losses during incubation are due to neglect, accidental breakage, and predation by Arctic foxes (*Alopex lagopus*), gulls, and infrequently even polar bears (*Thalarctos maritimus*). Survival rates and age of first breeding unknown.
Movements. Most northerly of the Atlantic auks. Mobile, undertaking migrations of substantial length. Abandons colonies end Aug. In winter, commonest in W Atlantic on S Grand Banks and shelf edge E of Nova Scotia, but scarce farther S, with distribution limits in E Atlantic less well defined. Two principal migratory patterns known: NW Greenland birds winter off Newfoundland; many from European Arctic winter off SW & (less frequently) SE Greenland, with massive westerly movement past NW Russia in Oct and return in Apr, presumably of birds from Novaya Zemlya, possibly from Severnaya Zemlya. Unlike others, Franz Josef Land birds appear to winter in NE Barents Sea, close to the breeding archipelago.
Status and Conservation. Not globally threatened. Believed to be the most abundant Atlantic auk, with most colonies situated in remote and inaccessible regions at high latitudes. Total breeding population estimated to number c. 12,000,000 pairs (8,000,000-18,000,000), with main concentrations located in: NW Greenland, with c. 10,000,000 in Thule region; E Greenland, with c. 500,000 in Scoresby Sound and Liverpool Land; W Spitsbergen with c. 1,000,000; Jan Mayen with c. 50,000; Franz Josef Land with 250,000; and NW Novaya Zemlya with c. 50,000. Human predation and disturbance at colonies is localized, and not thought to be serious at present; human exploitation worst in NW Greenland. Disturbance from offshore oil developments and transport gives some cause for concern, particularly developments on Newfoundland Grand Banks scheduled for 1997 (Hibernia and Terra Nova fields) and also continuing activity in Greenland, Svalbard region and Barents Sea. Widespread distribution of species reduces immediate risk from man-induced disturbance of marine ecosystems.

Genus *URIA* Brisson, 1760

2. Common Murre

Uria aalge

French: Guillemot marmette **German**: Trottellumme **Spanish**: Arao Común
Other common names: (Common) Guillemot, Thin-billed Murre

Taxonomy. *Colymbus aalge* Pontoppidan, 1763, Iceland.
Birds of Faeroes sometimes separated as race *spiloptera*. Proposed race *intermedia*, for populations of small islands in S Baltic, probably invalid, as claimed differences probably reflect individual variation. Five subspecies recognized.
Subspecies and Distribution.
U. a. aalge (Pontoppidan, 1763) - E North America, Greenland and Iceland, through Faeroes and Scotland to S Norway and Baltic Sea.
U. a. albionis Witherby, 1923 - Ireland and S Britain through Brittany to W Iberia; Helgoland.
U. a. hyperborea Salomonsen, 1932 - Svalbard through N Norway and Murmansk to Novaya Zemlya.
U. a. inornata Salomonsen, 1932 - E Korea and Japan (N Hokkaido) N through Sakhalin to Kamchatka, whence E through Bering Sea, Aleutians and W Alaska to NW British Columbia.
U. a. californica (H. Bryant, 1861) - N Washington S to California.
Winters mainly in boreal waters, S to Georges Bank and W Mediterranean, and to S Japan and S California.

Descriptive notes. 38-43 cm; mean 945-1044 g; wingspan 64-71 cm. Long, pointed, slender black bill with yellow mouth-lining, and dark brown iris; black to brownish head and upperparts, white underparts; white-tipped secondaries; legs and feet greyish black, with yellowish tinge beneath. Bridled or ringed morph has white eye-ring and post-ocular stripe; restricted to Atlantic, and most prevalent in N populations. Differs from *U. lomvia* in thinner bill which lacks white stripe. In winter, cheeks and underside of head and foreneck white, with dark spur behind eye; bill and feet paler. Juvenile similar to adult, but one third of size, with darker head. Second most differentiated alcid species, with races based largely on differences in plumage colour, degree of streaking, bill length, wing length and overall body size.
Habitat. Exclusively marine, occurring along sea coasts on rocky cliffs and offshore islands. Breeds mainly on steep sea cliffs and low, flat islands. Mostly offshore during winter, along edge of continental shelf and shallow banks, marine coasts and bays, generally in boreal waters but with some birds in cool subtropical zone; winter distribution largely determined by concentrations of schooling fish.
Food and Feeding. Mostly fish throughout year, supplemented to small degree by invertebrates: crustaceans, molluscs, polychaetes and fish eggs; daily intake 25-33% of adult body weight. Chicks fed almost exclusively fish except late in rearing period, when invertebrates may appear; 2-6 meals/day, averaging daily total of 20-32 g of fish, usually species high in fat and calorific value, e.g. capelin (*Mallotus*), herring (*Clupeus*), sprat (*Sprattus*) and sandeels (*Ammodytes*). Food usually obtained within 10-20 km of colony, infrequently up to 50 km away. Dives normally last under 60 seconds and to depths of 10-30 m, but 60-70 m recorded regularly, with maximum of 180 m exceptional.
Breeding. Spring arrival and start of laying variable, with relatively lengthy pre-laying period, longest in extreme S, shortest towards extreme N, determined largely by water temperature and ice; laying normally mid-May to early Jun, fledging mostly by late Jul to mid-Aug. Monogamous, with high mate and site fidelity. Highly colonial, in small to immense aggregations, usually at high density, reaching average of 20 pairs/m² on flat, rocky areas. Lays on broad or narrow cliff ledges and low, flat islands, and less commonly in crevices, under boulders and in caves; no nest, egg sitting on bare rock. 1 egg; incubation averages 32·5 days, by both sexes for periods of 12-24 hours; early egg losses replaced after 14-16 days; downy chick blackish brown above, white below, 55-95 g, semi-precocial; chick-rearing averages 20-22 days (16-30), with care and feeding by both parents until fledging, when adult male accompanies chick to sea; post-fledging parental care c. 4 weeks; female remains at breeding site for up to 2 weeks after chick departure. Breeding success variable within and between colonies, overall average usually 72-80% eggs laid producing fledglings; success greatly influenced by breeding density and synchrony, with performance highest where density and synchrony are high; age, experience and timing also important. Most egg and chick losses due to mishandling by adults, e.g. rolling or falling off ledge, and separation during fledging; also from gull predation. Adult survival 87-90%; survival of fledglings to breeding age variable, 17-41%. First breeding usually at 5 years, sometimes 4.
Movements. Winters offshore at sea, mostly within breeding range and some birds close to colonies; extends S to W Mediterranean and Gulf of Maine (casually to Virginia) in Atlantic, and to Korea, N Japan and S California (rarely to Baja California) in Pacific; N limits normally determined by ice conditions. Post-breeding dispersal highly variable: birds from Newfoundland, Irish Sea, Helgoland, Baltic and N Norway relatively sedentary, whereas those from N Britain, Faeroes and possibly Iceland move to W Norway and North Sea; no trans-Atlantic migrations known, though some Icelandic birds suspected to reach Greenland and E Grand Banks of Newfoundland. Pacific populations winter offshore near breeding colonies, except for N birds that move S after breeding, distance determined by weather and ice patterns. Most birds return to colonies Mar-Apr, rarely May in Labrador owing to ice break-up. In general, dispersal patterns often complex, requiring further examination, especially in N Atlantic.
Status and Conservation. Not globally threatened. Population sizes and trends relatively well known. Total population estimated at c. 9,000,000 pairs, with c. 4,000,000 (3,000,000-4,500,000) in Atlantic and c. 5,000,000 (4,000,000-5,500,000) in Pacific; c. 70% of total in S low Arctic zone, including large colonies in E Newfoundland, Iceland, Bear I and Alaska. High concentrations during and outside breeding season make species highly vulnerable to disturbance by human activities. Historically, world population severely reduced through 19th and early 20th centuries, mainly through egging and shooting at colonies, and introduced alien predators; species extirpated in many regions, particularly in S parts of range, during expansion in size and range of human population; some populations on verge of extinction, e.g. in NW Spain only 6-10 pairs in 1991. Slow recovery occurred over much of Atlantic

On following pages: 3. Thick-billed Murre (*Uria lomvia*); 4. Razorbill (*Alca torda*); 5. Black Guillemot (*Cepphus grylle*); 6. Pigeon Guillemot (*Cepphus columba*); 7. Spectacled Guillemot (*Cepphus carbo*); 8. Marbled Murrelet (*Brachyramphus marmoratus*); 9. Kittlitz's Murrelet (*Brachyramphus brevirostris*).

breeding range up to early 1970's with enactment of bird protection laws, except in N Norway, Faeroes and probably Iceland; little known of population size and status of birds in Pacific prior to early 1970's. Current status of entire population complex and variable; where long-term data exist, including W & E North America, N Europe and W Pacific, generally appears to be decreasing in most regions, in fewer instances stable. Since early 1980's, marked declines in C & N zones of California Current, stable numbers in Gulf of Alaska, and decreases in E Bering Sea. Major threats are unregulated hunting in Faeroes, Greenland and Newfoundland, overfishing of important forage species e.g. capelin, herring, cod and sandeels in N Atlantic (Barents Sea, Iceland, E Newfoundland and Grand Banks, Scotian Shelf and Gulf of Maine) and N Pacific, uncontrolled gill-net fisheries in NE Atlantic and N Pacific, and oil pollution and offshore petroleum developments in both oceans, e.g. Barents and North Seas, Greenland, E Newfoundland and Grand Banks, Alaska S to California. Changes in breeding numbers can be dramatic, e.g. Bear I population decreased by 85% from 250,000 to 36,000 pairs between 1986 and 1987, owing to collapse of Barents Sea capelin stock, and has since failed to recover. Detailed monitoring therefore required at major colonies, including Iceland, where status of largest Atlantic population is poorly known.

3. Thick-billed Murre

Uria lomvia

French: Guillemot de Brünnich **German**: Dickschnabellumme **Spanish**: Arao de Brünnich
Other common names: Brünnich's Guillemot/Murre

Taxonomy. *Alca Lomvia* Linnaeus, 1758, Greenland.
Considerable geographical variation through circumpolar range; biometric variation in general quasi-clinal, but high colour variation more difficult to interpret. Four subspecies recognized.
Subspecies and Distribution.
U. l. lomvia (Linnaeus, 1758) - NE Canada S to Gulf of St Lawrence, and Greenland E to Franz Josef Land, Novaya Zemlya and Severnaya Zemlya.
U. l. eleonorae Portenko, 1937 - E Taymyr Peninsula E to New Siberian Is.
U. l. heckeri Portenko, 1944 - Wrangel I, Herald I and N Chukotskiy Peninsula.
U. l. arra (Pallas, 1811) - N Pacific, from NW Alaska S to N Japan, Aleutians and SE Alaska.
Winters offshore and along sea coasts mainly in low Arctic waters, but some in N part of boreal zone S to Gulf of Maine, North Sea, Sea of Japan and Gulf of Alaska.

Descriptive notes. 39-43 cm; mean 810-1080 g; wingspan 65-73 cm. Largest extant alcid; blackish head and upperparts, white underparts; white-tipped secondaries; legs and feet greyish black, tinged yellowish beneath. Similar to *U. aalge*, but slightly larger in body size, with longer wings, shorter, heavier bill, and thicker head and neck (adult); differs in whitish line along cutting edge of upper mandible near gape, and the more acute-angled peak of white extending from upper fore-breast into neck-throat region; has no bridled or ringed morph. In winter, chin and throat white, producing dark-headed, almost capped appearance which separates from winter-plumaged *U. aalge* and *Alca torda*. Juvenile normally similar to winter adult, but about one third of size, with slightly darker chin, throat and underbody; some similar to breeding adult, with black throat and chin. Races based on differences in length of wing and tarsus, and length and depth of bill, averaging larger in E of breeding range; Pacific *arra* averages darker.
Habitat. Exclusively marine, occurring offshore and along sea coasts. Breeds on coastal cliffs and islands, and almost completely restricted to high and low Arctic zones with open water and adequate summer food supply; over 70% of population breeds in N parts of low Arctic water zone; colony locations usually associated with dynamic water systems, e.g. fronts, upwellings and converging currents, where primary and secondary productivity high. Winters mostly offshore to edge of continental shelf, and along sea coasts and in bays where concentrations of fish and invertebrates occur. At sea found in flocks, often large, likely related to non-random distribution of winter prey.
Food and Feeding. Chiefly fish, squid and crustaceans throughout year, supplemented by polychaetes and molluscs; invertebrates more significant than for *U. aalge*, particularly outside breeding season. Fish predominate during summer, main species varying with location: Arctic cod (*Boreogadus saida*) at high Arctic colonies (N Baffin Bay), and mix of Arctic and Atlantic cod (*Gadus morhua*) in low Arctic (Hudson Strait, Murmansk, Novaya Zemlya), often supplemented by other species including sculpins (Cottidae), pricklebacks (Gasterosteidae), capelin (*Mallotus villosus*) and infrequently Atlantic herring (*Clupea harengus*) and sandeels (*Ammodytes*). Daily intake c. 20-25% adult body weight. Chick diet almost entirely fish, with Arctic cod dominant (78-100%) at all high Arctic colonies, supplemented by sculpins (*Triglops*) and *Gammarus* amphipods and, to lesser extent, *Parathemisto* amphipods, *Gonatus* squid and *Harmothoe* polychaetes; invertebrates always under 7% of food. In low Arctic, Arctic cod still important, but less so than in high Arctic: 51% (Digges I, Hudson Bay; Novaya Zemlya) and 35% (Akpatok I, Ungava Bay) in N of zone, but only 2% at S location (Gannet Is, Labrador), where capelin, blennies and other benthic species predominate; also significant were blennies and sculpins (Akpatok), Atlantic cod and herring (Novaya Zemlya), and herring, capelin and daubed shanny (Jan Mayen). Chick feeding rates variable, generally c. 4-5 meals/day (1-8) with average daily intake of c. 58 g of fish (Prince Leopold I: chicks 3-20 days old). Food obtained close to colony, usually within 30-50 km, but often as far away as 100 km or more; distance determined by prey density and movements, as well as ice cover. Average dive times vary with location: 40-50 seconds (Novaya Zemlya), 29 seconds (Lancaster Sound and Baffin Bay: maximum 75), 83 seconds (Lancaster Sound: maximum 192). Dives under 60 seconds to depths of 10-30 m, but 50-70 m probably not unusual, with 100 m or more exceptional; prevalence of benthic fish indicates regular visits to sea floor area, often at considerable depths.
Breeding. Spring arrival and start of laying variable, usually related to sea temperatures, with laying latest where temperatures lowest; in mixed *Uria* colonies, timing similar between species. Median laying dates in both Arctic zones similar, usually late Jun to early Jul, slightly earlier towards S edge of low Arctic water: in E Canada, late Jun to early Jul in high Arctic (Prince Leopold I, Coburg I, and Cape Hay, Bylot I), end Jun in N low Arctic (E Digges I), and late Jun in S low Arctic (Gannet Is, Labrador); earlier towards S limit of low Arctic water and in N boreal waters, late May to early Jun (e.g. E Murmansk and Novaya Zemlya). Fledging mostly peaks by mid- to late Aug, earlier in S low Arctic and boreal zones. Highly colonial, usually in immense aggregations and at high densities on steep sea cliffs, but normally at densities below those of *U. aalge*. Lays on narrow ledges; no nest, egg laid on bare rock. 1 egg; incubation averages 32-33 days, by both sexes, for stints of 12-24 hours, infrequently 48 hours; most early eggs losses replaced, usually after 14 days (11-17); downy chick blackish brown, white on belly, with white-streaked head, 65-70 g, semi-precocial; chick-rearing averages 21 days (16-30), with brooding, guarding and feeding by both parents until fledging, when male parent accompanies chick to sea; post-fledging parental care at least 4 weeks, probably up to 8-12 weeks; female remains at breeding site for 2 weeks or more after chick departure. Breeding success variable between years and colonies, normal average c. 70-80% of eggs laid producing fledglings, early breeders more successful than later breeders. Most failures due to egg loss, largely from mishandling by adults at laying or during change-overs, causing egg to fall off ledge; eggs and some chicks also lost to predators, e.g. Glaucous Gull (*Larus hyperboreus*), Common Raven (*Corvus corax*), arctic fox (*Alopex lagopus*). Adult survival c. 91%; survival of fledglings from departure to wintering grounds c. 40%, to breeding age 24-37%. First breeding normally at 5 years, infrequently 3 or 4 when colony small and expanding.
Movements. Winters mostly offshore at sea, mainly in low Arctic waters, but some in N of boreal zone S to North Sea and N Europe (occasionally to Britain and Netherlands, rarely France), Gulf of Maine (to Long I, infrequently to South Carolina), Gulf of Alaska and British Columbia (casually Washington S to California), and Sea of Japan (Hokkaido); dispersal determined largely by ice conditions and food availability. In Atlantic two major migratory pathways, associated with Labrador Current and E to W Greenland Currents: birds from Arctic Canada and W Greenland move S to E Newfoundland (shelf and Grand Banks) and Nova Scotia; those from European Arctic move SW towards W Greenland, including Spitsbergen birds that reach both SW Greenland and Newfoundland waters and remain until Mar. In N Pacific, birds likely remain close to breeding areas except where ice conditions interfere, with most wintering in C & S Bering Sea and fewer in Gulf of Alaska or Seas of Okhotsk and Japan; some regularly winter in E Chukchi Sea N to Cape Thompson and Point Hope, but most birds probably move SW to Bering Sea. Return begins in Mar, most birds back at colonies between mid-Apr and late May, sometimes later owing to late break-up of sea ice. Dispersal patterns poorly known in many regions, especially European Arctic and many parts of N Pacific.
Status and Conservation. Not globally threatened. Total breeding population estimated at c. 11,000,000 pairs, with c. 6,500,000 (4,900,000-7,500,000) in N Atlantic and 4,500,000 (3,500,000-6,000,000) in N Pacific and Chukchi Sea. In Atlantic, c. 25% of population in NW, with especially large colonies in E Canadian Arctic (Hudson Strait, Lancaster and Jones Sounds) and NW Greenland; remainder in NE Atlantic, concentrated in Iceland, Bear I, Spitsbergen, Franz Josef Land and Novaya Zemlya. Almost 80% of Pacific population in NE, particularly E Bering Sea, e.g. Pribilofs, St Lawrence I, St Matthew I; NW portion largely in W Bering Sea (554,000 pairs), with smaller numbers in Sea of Okhotsk (c. 210,000 pairs, with major colonies on Matykyl and Talan Is) and W Chukchi Sea (c. 140,000 pairs). Most colonies in Bering and Okhotsk Seas mixed with *U. aalge*, as are some in Chukchi Sea. High aggregations during and outside breeding season make species highly vulnerable to human activities. Information on population sizes from 19th century is both scarce and qualitative; since early 1900's, population severely reduced due to human exploitation and disturbance. In Atlantic, information since 1930's clearly indicates major declines in many parts of range, notably: E Canadian Arctic, where probably 20-40% decline mid-1950's to late 1970's; W Greenland, 35-50% decline 1930-1990 and continuing, with many colony extinctions occurring or imminent; and Novaya Zemlya, reductions by 40-50% from 1930 to late 1940's; decreases at other sites suspected, e.g. Iceland, Jan Mayen. E Canadian population apparently now stable, as seems the case at Novaya Zemlya, albeit at markedly reduced levels. Data for N Pacific and Chukchi Sea sparse before mid-1970's, since when trends indicate declines in E Bering Sea (e.g. Cape Pierce, Pribilofs) and relative stability elsewhere following large declines through human activity (commercial egging, hunting, cliff habitat alteration) from late 1940's to 1960 (Sea of Okhotsk); trends for Chukchi Sea variable, both declines (Cape Thompson, 1960-1979) and slight increases (Cape Lisburne, 1976-1987) recorded, but all populations there now believed to be stable. Main threats to world population during first half of 20th century were direct and indirect human exploitation: egging, hunting, disturbance, and introduction of mammalian predators (N Pacific). Current threats remain man-induced: unregulated hunting in Newfoundland and Labrador (winter) and Greenland (summer and winter); incidental kills in fishing nets; competition with commercial fisheries, notably in Barents Sea, Iceland, E Newfoundland and Grand Banks, Bering Sea, Gulf of Alaska, Sea of Okhotsk; introduced predators, N Pacific; and oil pollution and offshore oil developments in many areas, e.g. Barents Sea, North Sea, Greenland, E Newfoundland and Grand Banks, Scotian Shelf, Alaska S to California, W Bering Sea, Sea of Okhotsk. Immediate conservation requirements include: enhanced monitoring of major colonies, particularly in Greenland, Iceland, Spitsbergen, Russian Arctic and Alaska, where population size and status inadequately known; further development and refinement of census methods to deal with separation of species at large mixed *Uria* colonies, especially in N Pacific; regulation of hunting in E Canada and Greenland; detailed assessment of impacts of overfishing by commercial fisheries in both oceans, particularly of capelin, cod, herring and sandeels in Barents Sea, Iceland, E Newfoundland and Grand Banks, and Bering Sea; continuation and expansion of assessment of by-catch in gill-net fisheries, particularly in NE Atlantic and N Pacific; development of tighter legislation and penalties (national and international) associated with oil pollution from offshore developments and transport, as well as expansion and refinement of monitoring schemes to assess bird mortality; and eradication of alien predators, especially foxes at N Pacific Alaskan and Russian colonies. Population problems and conservation needs similar to *U. aalge*. Overall, main need is rapid reduction of human activities that seriously threaten future of species and health of marine ecosystems.

Genus *ALCA* Linnaeus, 1758

4. **Razorbill**

Alca torda

French: Petit Pingouin **German**: Tordalk **Spanish**: Alca Común
Other common names: Razor-billed Auk

Taxonomy. *Alca Torda* Linnaeus, 1758, Stora Karlsö, Baltic Sea.
Populations of E Canada, W Greenland, Norway and Murmansk described as race *pica*, having additional furrow on upper mandible, but not valid as this characteristic now known to be age-related. Two subspecies recognized.
Subspecies and Distribution.
A. t. torda Linnaeus, 1758 - E North America (Digges Sound and SE Baffin S to Gulf of Maine), Greenland and E to Bear I, Norway, Denmark, Baltic Sea region, Murmansk and White Sea.
A. t. islandica C. L. Brehm, 1831 - Iceland, Faeroes, Britain, Ireland E to Helgoland, Channel Is and NW France (Brittany).
Winters mostly offshore and along sea coasts in N part of boreal water zone, S in W Atlantic to Long I (New York), casually to South Carolina and Florida; in E Atlantic, from S Norway and Baltic to W Mediterranean.

Descriptive notes. 37-39 cm; 524-890 g; wingspan 63-66 cm. Similar to *Uria*, but body and wings average slightly smaller, with head and bill larger, appearing distinctly rectangular; coloration also similar, but normally upperparts darker, dark extends farther onto breast, and thicker bill shows diagnostic markings: broken transverse white line across both mandibles, with prominent white line extending from base of culmen to eye; bill otherwise mostly black, with pronounced transverse ridges or furrows on upper mandible (older birds have more ridges); legs and feet blackish grey, with black claws. Female averages slightly smaller. In winter, throat, cheeks and earcoverts white; white line between eye and bill absent. Juvenile similar to winter adult, but cheeks, earcoverts, throat and sides of breast with darkish streaking; transverse white line across bill less distinct. Races based on differences in body size, bill length and depth, and wing length; *islandica* smaller.
Habitat. Marine, occurring offshore and along sea coasts in boreal or low Arctic waters. Breeds in rocky coastal regions on steep mainland cliffs and rocky offshore islands. Winters offshore from breeding areas, often at considerable distances, but normally only to edge of continental shelf, and extending farther S into warmer waters (N cool subtropical zone) than *Uria* species in both W & E Atlantic; in flocks at sea, often mixed with *Uria*, probably owing to similarity of winter diets and patchiness of prey distribution.
Food and Feeding. Mainly fish and crustaceans throughout year. Considerable geographical and temporal variation in principal prey during summer: in Labrador, initially almost 100% fish, mainly capelin (*Mallotus villosus*), whereas during chick-rearing sculpins (*Myxocephalus*) and euphausiids dominate; in Murmansk, diet mainly fish, i.e. (in descending importance) Atlantic herring (*Clupea harengus*), Atlantic cod (*Gadus morhua*), sandeels (*Ammodytes*) and capelin, with small amounts of crustaceans and polychaetes; in White Sea sandeels predominate, followed by capelin and some Atlantic herring. In winter, diet variable, largely fish in Baltic (clupeids, gobies, and fewer garfish, gadids and sticklebacks, 20% crustaceans) and crustaceans in Newfoundland. Chick fed almost exclusively fish, average 2-5 meals/day, usually totalling 20-25 g, generally of species with highest calorific value: in low Arctic waters normally sandeels, with capelin of secondary importance (Labrador, Gulf of St Lawrence, White Sea); at boreal locations mainly sprat (*Sprattus sprattus*), supplemented by young herring and rarely sandeels (Irish Sea, Baltic). Food normally obtained near colony, usually within 15 km, sometimes as close as 2 km, with fish carried crosswise in bill on return flight. Dives normally under 60 seconds to shallow depths, usually 5-7 m, but regularly to 10-15 m, with maximum of 120 m exceptional.
Breeding. Timing variable, with laying earliest at S extremes of range, e.g. Wales from early May; later at higher latitudes where waters colder, e.g. Murmansk mostly early Jun, Labrador mid- to late Jun; timing related more to surface-water temperature than to latitude. Monogamous, with high mate and breeding site fidelity. Loosely colonial, in small to large groups from a few pairs to 100's, infrequently 1000's, usually mixed with other colonial seabird species; normally at relatively low densities owing to nature of breeding habitat. Lays mostly in crevices in boulder fields and rock rubble, but often in rock crevices on cliff faces or exposed ledges; no nest, egg sometimes laid in a rough. 1 egg; incubation averages 35-37 days, by both sexes probably for bouts of c. 12-24 hours; eggs lost early may be replaced after c. 14 days; downy chick mottled brown and buff above, white below with brown-mottled flanks, with much white on head, c. 60 g, semi-precocial; chick-rearing averages c. 18 days (17-19), with care and feeding by both parents until fledging, when adult male accompanies chick to sea; post-fledging parental care at least 3 weeks. Breeding success variable, 62-85% eggs laid producing fledglings, average probably c. 70%, with egg loss greater than chick mortality; timing of breeding, quality of breeding site, and age of female parent all affect success. Adult survival 89-92%; survival of fledglings to breeding age 16-33%. First breeding at 4-5 years.
Movements. Winters mostly offshore at sea, in W Atlantic off E Newfoundland as far as Flemish Cap (c. 700 km offshore), off S Nova Scotia S regularly to North Carolina, and common on Georges Bank off New England. In E Atlantic, movements outside breeding season roughly similar to those of *Uria aalge*, but extends farther S. Overall, N populations move S or SW: Greenland and Labrador birds to offshore E Newfoundland and SW to Gulf of Maine and farther S, those from Barents and White Seas to Skagerrak, like Baltic breeders. N British birds first move to SW Norway and North Sea (young birds later to Bay of Biscay), whereas those from Irish Sea move S to Bay of Biscay and W Mediterranean. Most birds return to colonies from mid-Apr to early May in W Atlantic, except where ice persists longer (e.g. Labrador), and between early Mar and mid-Apr in E Atlantic, though some colonies reoccupied by late Feb or earlier. Dispersal patterns complex, requiring further study of birds at sea outside breeding season on both sides of Atlantic.
Status and Conservation. Not globally threatened. Total breeding population estimated at c. 700,000 pairs (300,000-1,200,000), with roughly 70% in Iceland, 20% in Britain and Ireland, and remainder divided between E (7%) and W (3%) Atlantic. Population sizes and recent changes relatively well known in NW Atlantic, Britain and Ireland and N Europe, less so at centre of breeding range in Iceland. Widespread declines known to have taken place throughout N Atlantic since early 1900's, probably starting in 19th century through human disturbance, particularly egging and hunting. In general, reductions continue in S range, particularly Gulf of St Lawrence, E Newfoundland and Labrador, Greenland, Norway and France, except in British Is, where appears to have increased between 1969/70 and 1985-1987; present status in Iceland and Faeroes uncertain, though decline of 60-75% may have occurred in Faeroes between 1960 and early 1980's. Major threats now are: unregulated hunting, in Labrador, Gulf of St Lawrence, Newfoundland, Greenland, Faeroes and Norway; uncontrolled gill-net fisheries in summer in most of breeding range, and gill-netting of birds on wintering grounds in Kattegat and Iberia; overfishing of important prey species and alteration of marine ecosystems, in Gulf of St Lawrence, E Newfoundland and Grand Banks, Georges Bank, North Sea, Barents Sea; and oil pollution and offshore petroleum developments on both sides of Atlantic, in Barents and North Seas, Greenland, E Newfoundland and Grand Banks, Scotian Shelf. Also vulnerable as 70% of world population concentrated in one area, Iceland; relatively small total population. Most important conservation need is rapid establishment of integrated international monitoring system to measure changes in population size and status in Iceland, British Is, Norway and E North America.

Genus *CEPPHUS* Pallas, 1769

5. **Black Guillemot**

Cepphus grylle

French: Guillemot à miroir **German**: Gryllteiste **Spanish**: Arao Aliblanco
Other common names: Tystie

Taxonomy. *Alca Grylle* Linnaeus, 1758, Baltic Sea.
Forms superspecies with *C. columba*. Considerable geographical variation throughout range, with subspecific limits uncertain. Five subspecies recognized.
Subspecies and Distribution.
C. g. mandtii (Mandt, 1822) - Arctic E North America S to Labrador and N Newfoundland, W & E Greenland, Jan Mayen and Svalbard E through E Siberia to N Alaska.
C. g. arcticus (C. L. Brehm, 1924) - North America (S of *mandtii*) and S Greenland to British Is, Norway, SW Sweden, Denmark, Murmansk and White Sea.
C. g. islandicus Hørring, 1937 - Iceland.
C. g. faeroeensis (C. L. Brehm, 1831) - Faeroes.
C. g. grylle (Linnaeus, 1758) - Baltic Sea.
Winters close to breeding area except where water frozen over: casual S to Long I and New Jersey and to N France.

Descriptive notes. 30-32 cm; 450-550 g; wingspan 52-58 cm. Slender, pointed black bill with red mouth-lining; plumage entirely black, except for white upperwing patch and white underwing-coverts; bright vermilion legs and feet; occasional individuals lack white wing patch. Distinguished from *C. columba*, by lack of dark bands in upperwing patch and by whiter underwing. In winter, head and underparts mostly white, with upperparts speckled greyish brown and white. Juvenile resembles winter adult, but has mottled upperwing patch, with brown-tipped coverts. Races based on complex differences in morphometric characters, often quasi-clinal, involving wing length, bill length and depth, and plumage, including amount of white in upperwing.
Habitat. Exclusively marine, rarely in brackish water, along rocky sea cliffs and shores. Breeds in all marine waters N of cool subtropical zone, usually close to areas of shallow water, often at considerable height on cliffs. Mostly pelagic in winter, close to breeding area (except N populations, which are influenced by ice cover), with movements inshore to sheltered waters; some individuals overwinter at high latitudes in polynyas and leads in ice.
Food and Feeding. High diversity of benthic fish and invertebrates, found on or near sea floor in shallow water. Mostly small demersal and pelagic fish, young of larger fish, and vast variety of invertebrates including: polychaetes, pteropods, jellyfish, lamellibranchs, sponges and ctenophores and crustaceans (copepods, amphipods, decapods, euphausiids, isopods and mysids). Winter diet poorly known, probably higher proportion of invertebrates (crustaceans, polychaetes, molluscs) than fish overall. Chick diet largely fish, except in high Arctic regions, where crustaceans can comprise 25-30% (by weight) of diet: normally, blennies (Pholidae, Strichaeidae, Zoarcidae), gobies (Gobiidae), sculpins (Cottidae), Arctic cod (*Boreogadus saida*) and sea snails (Cyclopteridae) predominate in Arctic regions, and sandeels (*Ammodytes*) at boreal locations, less frequently clupeids, osmerids, rockfish (Scorpaenidae), flatfish (Pleuronectidae) and wrasse (Labridae). Chick-feeding rates widely variable, from averages of 3 meals/day (Barents Sea) to 7-15 (White Sea), 5·3-14 (SW Finland) to 15 (Iceland) and 12·4 (Gulf of St Lawrence). Feeds mainly inshore, during summer usually within 4 km of breeding site, sometimes farther. Diving times average 25-40 seconds, with maxima of 75-146 seconds exceptional, to depths of normally less than 20 m.
Breeding. Median laying usually between late May and mid-Jun, sometimes earlier (N Norway) or later (Spitsbergen, Franz Josef Land, Novaya Zemlya) owing to water characteristics; fledging mostly Aug. Monogamous, with high mate and site fidelity; annual divorce rate 5-7%. Normally breeds at low density in small scattered groups of 5-100 pairs, or singly; in N of range some groups large, exceeding

1000 pairs. Lays in rough scrape at back of crevices and cavities in cliff face, scree slopes and boulder fields; often at considerable height on cliffs. 2 eggs, sometimes 1; incubation averages 28-32 days (1st eggs 31 days, 2nd eggs 28 days), by both sexes for shifts of several hours; early egg losses may be replaced after c. 15 days; downy chick blackish brown, slightly paler below, c. 40 g, semi-precocial; chick-rearing averages 34-39 days (30-40), with care and food provisioning shared by parents until fledging, when chicks fly out to sea unaccompanied. Breeding success variable within and between breeding locations, overall averages 66% for hatching and 68% for fledging; mean annual productivity (fledged young/pair) varies from 0·0-0·6 (Finland, Denmark) to 0·7-0·9 (Bay of Fundy, Gulf of St Lawrence, Prince Leopold I) and 1·2-1·6 (Iceland, White Sea). Main causes of egg and chick loss are predation, mostly by introduced mink (*Mustela vison*) and rats (*Rattus*), adverse weather and flooding of breeding sites, and starvation. Adult survival 81-87%; survival of fledglings to breeding age 16-32%. First breeding usually at 4 years, sometimes 2 or 3.

Movements. Resident and mostly sedentary except in N regions, where movement to adjacent ice-free waters occurs. In general, winter distribution of adults essentially as breeding, with concentrations at traditional locations to moult, usually in sheltered waters near colony, where they spend winter. Fledglings often move considerable distances from natal sites, usually in direction of prevailing sea currents; reasons for their long distance dispersal unclear. Overall, dispersal patterns of the various populations poorly known, particularly in remote and inaccessible regions; better known in S of range, e.g. N Britain.

Status and Conservation. Not globally threatened. Breeding population size unknown, but conservative estimate in 1985 of 270,000 pairs (200,000-350,000) with largest numbers in N, including 50,000 in E Canadian Arctic, 40,000 in Greenland and 50,000 in Iceland. Most breeding groups small, but large colonies known in high Arctic, e.g. 4000 pairs on Prince Leopold I and 10,000 pairs at Skuis Point (Devon I). Population sizes and trends only poorly known. Species relatively difficult to census owing to low breeding density and colony-attendance patterns; inter-year count comparisons therefore difficult, and often unreliable. Current status in Arctic regions unknown; farther S, declines recorded in W Norway and E Canada since mid-1930's, though stable or increasing at S edge of range in British Is (Irish Sea, Firth of Clyde) and NE USA (New England). Wide distribution and dispersal patterns safeguard the species from human disturbance, but local impacts from introduced predators (e.g. mink, rats), oil spills, and commercial gill-net fishing can be serious.

6. Pigeon Guillemot

Cepphus columba

French: Guillemot colombin **German**: Taubenteiste **Spanish**: Arao Colombino
Other common names: Sea Pigeon

Taxonomy. *Cepphus Columba* Pallas, 1811, Kamchatka and Bering Strait.
Forms superspecies with *C. grylle*. Race *snowi* sometimes considered a megasubspecies. Five subspecies recognized.

Subspecies and Distribution.
C. c. columba Pallas, 1811 - Kamchatka N to Bering Strait and W Alaska.
C. c. snowi Stejneger, 1897 - Kuril Is.
C. c. kaiurka Portenko, 1937 - Commander Is to WC Aleutian Is.
C. c. adianta Storer, 1950 - C Aleutian Is S to Washington.
C. c. eureka Storer, 1950 - Oregon and California.
Winters mostly at sea and along coasts, from S Bering Sea and S Alaska S to Japan and S California.

Descriptive notes. 30-37 cm; 450-550 g. Bill long, straight and pointed, black with bright red mouth-lining; dark blackish brown plumage, with dark brown wedge in white upperwing patch, and dusky grey underwing; legs and feet vermilion, claws black. In winter, upperparts greyish with white barring, underparts mostly white. Juvenile similar to winter adult, with white wing patch often obscured. Races based largely on trends in morphometric characters, with culmen and wing lengths decreasing from S to N (except in Bering Sea and Siberia) and white in outer primary and underwing-coverts increasing; *snowi* commonly has white in upperwing reduced or absent.

Habitat. In summer along rocky coastlines, breeding on sea cliffs and slopes close to regions of shallow water usually less than 50 m deep. Along rocky sea coasts in winter, often in sheltered coves; leads and openings in ice used regularly in Bering Sea and S Alaska.

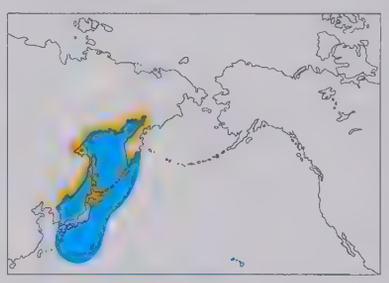
Food and Feeding. Wide variety of small benthic fish and invertebrates (shrimp, crabs, sometimes polychaetes, gastropods, bivalve molluscs) throughout year; winter diet more diverse. Chicks usually fed fish, predominantly sandeels (*Ammodytes*), herring (Clupeidae), gadids, gunnels/pricklebacks (Xiphisteridae, Lumpenidae), eelpouts (Zoarcidae), sculpin (Cottidae), rockfish (Scorpaenidae), and flatfish (Bothidae, Pleuronectidae), usually obtained within 1 km of colony; provisioning rate varies with brood size and age, average 0·7-1·9 fish/hour/nest in Alaska and British Columbia. Dive times 10-144 seconds, optimal efficiency in water depths of 10-20 m.

Breeding. Normally arrives early Mar in California, Apr in British Columbia, 40-50 days before first eggs; peak laying mid-May to mid-Jun in California and British Columbia, 1-2 weeks later in Alaska. Monogamous, with high mate (probably) and site fidelity. Usually in small colonies of under 50 birds, sometimes as single pairs; concentrations of over 1000 birds exceptional. Nests in crevices and cavities on cliffs, talus slopes and rock rubble, sometimes excavating burrow. Usually 2 eggs; incubation averages 29 days (29-32) for 1st and single eggs, 27 days (26-32) for 2nd eggs, by both sexes in shifts of 2-4 hours (up to 17); downy chick blackish brown, c. 38 g, semi-precocial; chick-rearing averages c. 38 days (30-53), with care and feeding by both parents; chicks independent at fledging, when they fly to sea alone. Breeding success and annual productivity highly variable between years, 0·2-1·5 fledglings/pair. Adult survival averages 80% (76-89%); survival of fledglings to breeding age c. 40%. First breeding usually at 4 years, sometimes 3, rarely earlier.

Movements. Spring and autumn migrations poorly known, as are details of winter range. Generally winters at sea and along coast from Pribilofs and Aleutians (Bering Sea) S to N Japan (Hokkaido) and S California. Most birds from British Columbia, Washington, Oregon and Kuril Is remain near breeding grounds during winter; those from California and Alaska move N and S, respectively. Main migration periods likely Oct and Mar.

Status and Conservation. Not globally threatened. Population size estimated at c. 235,000 birds (1993), with largest numbers on Farallon Is (California) and Chukotskiy Peninsula. Local populations vulnerable to oil pollution, drowning in gill-nets, and introduction of mammalian predators to colonies; widespread distribution believed to offset local threats. Vulnerability to oil considered high, but impact on population size and breeding unclear. Numbers reduced in parts of California by oil pollution and human disturbance, also by food shortages in warm-water years in California and Oregon; relatively stable elsewhere, except for Prince William Sound, Alaska, where steady decline in breeding birds has occurred since 1972 from unknown causes but also from Exxon Valdez oil spill in 1989. Inshore gill-net fisheries can cause significant local mortality, as can introduced mammalian predators on islands. Status of NW Pacific population unknown.

Bibliography. Ainley & Boekelheide (1990), Ainley & Lewis (1972, 1974), Armstrong (1983), Bent (1919), Brazil (1991), Drent (1965), Emms (1987), Emms & Morgan (1989), Emms & Verbeek (1989, 1991), Ewins (1993), Ewins *et al.* (1993), Follet & Ainley (1976), Gould *et al.* (1982), Hodder & Graybill (1985), King (1984), King & Sanger (1979), Knystautas (1993), Koelink (1972), Kondratiev (1991), Lehnhausen (1980), Lensink (1984), Litvinenko & Shibaev (1991), Manuwal (1984), Mayr & Short (1970), Nelson (1982, 1987, 1991), Oakley (1981), Page *et al.* (1990), Piatt, Lensink *et al.* (1990), Richards (1990), Rodway (1991), Sowls *et al.* (1978), Storer (1950, 1952), Thoresen (1989), Thoresen & Booth (1958), Trapp (1985), Vermeer, Briggs *et al.* (1993), Vermeer, Morgan & Smith (1993a, 1993b).



7. Spectacled Guillemot

Cepphus carbo

French: Guillemot à lunettes **German**: Brillenteiste **Spanish**: Arao de Anteojos
Other common names: Sooty/Bridled Guillemot

Taxonomy. *Cepphus Carbo* Pallas, 1811, Kuril Islands.
Monotypic.

Distribution. Coasts and islands of NW Pacific, from Kamchatka and Sea of Okhotsk S to NE Korea, Kuril Is, and N Japan (Hokkaido, N Honshu). In winter, pelagic and coastal, usually near breeding locations and somewhat farther S.

Descriptive notes. c. 38 cm; 490 g; wingspan 65·5-69 cm. Largest of *Cepphus* guillemots, plump and grebe-like, with long, thick neck and relatively short, robust, pointed black bill; dull sooty blackish brown, with conspicuous white "spectacle" patch around eye and small whitish area at base of bill; legs and feet red. In winter, crown mottled grey and white and underparts mostly white. Juvenile similar to non-breeding adult, but with brownish black cross-bars on underparts.

Habitat. Exclusively marine; near-shore, breeding along rocky mainland coasts in cliffs or on slopes and boulder fields, or in more accessible sites on predator-free islands; most breeding sites close to shallow water suitable for foraging in food-rich areas of vegetated or rocky benthos. In winter mostly pelagic, along coasts.

Food and Feeding. Chick diet largely fish, with wide diversity of benthic species, sardines (*Sardinops*) and herring (Clupeidae), plus a few invertebrates. Adult diet probably similar; winter diet of adults and juveniles little known. Feeds mainly inshore along coast, usually close to breeding area; in summer, adults forage in shallow water (15-20 m) and tidal rifts and races, usually within 6 km of breeding site.

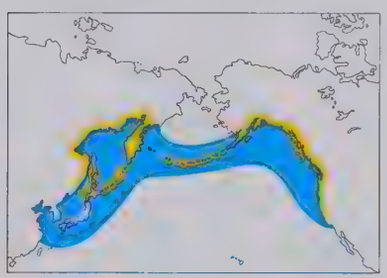
Breeding. Less known than any other alcid species. Timing uncertain: most birds probably arrive Apr-May; laying probably begins mid-May, with hatching mid-Jun to early Jul; fledglings not seen at sea before 2nd week of Aug. Believed monogamous, with mate and site fidelity similar to other *Cepphus*. Breeds usually in groups of 10-20 pairs, sometimes as single pairs, and rarely in large colonies of 200-300 pairs. Lays in cliff crevices, in holes and cavities in scree slopes and boulder fields, or in more accessible sites on predator-free islands; in S Ussuriland many nests found among boulders 1·5-20 m above high water line, with fewer in cliff crevices or under shrubs and tree roots up to 120 m from sea, whereas at Teuri I over 60% of nests more than 20 m above sea-level. Normally 2 eggs, sometimes 1; incubation averages c. 28 days (possibly 30-33), by both sexes, length of shifts unknown; chick c. 40 g, semi-precocial; chick-rearing period uncertain, but 1 chick fledged at 33 days. Breeding performance and annual productivity not known, probably low. Eggs and small chicks taken by Large-billed Crows (*Corvus macrorhynchos*), Common Ravens (*Corvus corax*) and Slaty-backed Gulls (*Larus schistisagus*), adults sometimes by Northern Eagle-owls (*Bubo bubo*) and Peregrine Falcons (*Falco peregrinus*); introduced predators, especially foxes (*Alopex lagopus, Vulpes vulpes*), sable (*Martes zibellina, Lamprogale flavigula, Kolnocus sibirica*), and rats (*Rattus*) can cause colony to be abandoned. Survival rates and age at first breeding unknown.

Movements. Resident and mostly sedentary, remaining in vicinity of colony, except in N areas. Pronounced movement from Peter the Great Bay in Aug and Sept (to moulting areas?), and most Sea of Okhotsk birds are forced S by ice formation, usually by early Dec; influx into Sea of Japan in early Sept believed to be related to N exodus. Also S movement along coasts of Japan in winter, probably mostly juveniles. In spring, reverse movement of adults probably complete by late Apr, with immatures arriving later. Winter distribution and movements little known.

Status and Conservation. Not globally threatened. Approaching near-threatened status. Conservative rough estimate in 1993 gives total breeding population of 71,000-74,000 pairs, with 89% in Sea of Okhotsk and remainder in Sea of Japan. Largest known concentrations at Shantarsky Is (18,000-20,000 pairs), Peter the Great Bay (c. 5500 pairs), and Matykyl I (c. 4000 pairs). Limits of breeding range reasonably well known, but in numerous parts of Sea of Okhotsk and W Kamchatka breeding is only suspected and requires confirmation. Overall, the least numerous inshore-feeding alcid in N Pacific. Population decreasing, and marked declines recorded recently at several locations: 10-20% annual reductions at colonies around Hokkaido; 93% decline at Teuri I in period 1963-1987; and 53% decrease on Furugelm I since 1979. Causes of declines uncertain, but introduced mammalian predators (foxes, sable, rats) and reductions in forage fish stocks seem likely factors; human disturbance of breeding habitat and illegal hunting may also be involved. Offshore oil developments in Sea of Okhotsk pose additional threat. Immediate conservation needs: systematic surveys early in season (pre-breeding) to assess distribution and size of breeding populations; post-breeding surveys to identify locations of moult concentrations of flightless birds; and initiation of colony and at-sea studies to determine species' ecological requirements throughout year.

Bibliography. Austin (1948), Brazil (1991), Dementiev & Gladkov (1951b), Elsukov (1984), Étchécopar & Hüe (1978), Ewins *et al.* (1993), Flint *et al.* (1984), Gizenko (1955), Hasegawa (1984), Knystautas (1993), Kondratiev (1991), Kozlova (1957), Litvinenko & Shibaev (1991), Nazarov & Labzyuk (1972), Nechaev (1986), Roslyakov (1986), Shibaev (1987), Shuntov (1986), Storer (1952), Thoresen (1984), Udvardy (1963), Velizhanin (1969, 1975, 1977), Vyatkin (1986), Vyshkvartsev & Lebedev (1986), Watanuki *et al.* (1988).

Genus *BRACHYRAMPHUS* M. Brandt, 1837



8. Marbled Murrelet

Brachyramphus marmoratus

French: Guillemot marbré **German**: Marmelalk **Spanish**: Mérgulo Jaspeado
Other common names: Long-billed Murrelet

Taxonomy. *Colymbus marmoratus* Gmelin, 1789, Prince William Sound, Alaska.
Recent work suggests race *perdix* may be distinct species, but evidence incomplete and further examination required. Two subspecies recognized.

Subspecies and Distribution.
B. m. perdix (Pallas, 1811) - Kamchatka and Sea of Okhotsk S to N Japan (Hokkaido).
B. m. marmoratus (Gmelin, 1789) - W Aleutians (Attu I) to Barren Is and SE Alaska, S to C California (Santa Cruz Mts).
Winters mainly offshore and along coasts near and somewhat S of breeding grounds.

Descriptive notes. 24-26 cm; 220 g (196-269 g). Chunky alcid with slender, pointed blackish bill, and blackish brown iris; dusky dark brown crown and upperparts, back feathers tipped with rusty brown; entire underparts mottled brown and white, sometimes forming indistinct brownish breast band; legs and feet flesh-coloured, with darker webs. Distinguished from *B. brevirostris* by longer bill, more uniform upperparts and darker belly. Winter adult blackish above, with black cap extending below eye (unlike *B. brevirostris*), narrow white band from cheeks around nape, white scapular patches; underparts mainly white. Immature similar to winter adult, but white underparts finely streaked dusky brown. Race *perdix* larger (c. 50-70 g heavier), with markedly longer bill and wing; in summer plumage, lacks rusty brown tones above, and outermost rectrix has narrow white marginal stripe (lacking in nominate race).

Habitat. Pelagic and along sea coasts, in summer usually offshore from coniferous forests along mainland coast and islands. Breeds in old-growth and late successional coniferous forests, usually within 60 km of coast, with western hemlock (*Tsuga heterophylla*), Sitka spruce (*Picea sitchensis*) and Douglas fir (*Pseudotsuga menziesii*) the most important nest trees; less frequently on bare ground, usually on inland slopes, in boreal tundra regions along sea coasts (e.g. NW Gulf of Alaska). At sea, found inshore to offshore as widely spaced pairs or in flocks associated with ocean processes such as upwellings, converging currents and river plumes. In winter, mostly inshore in sheltered and productive coastal waters within or adjacent to breeding range; also uses coastal lakes year round.

Food and Feeding. Adult diet normally invertebrates, especially euphausiid crustaceans (*Thysanoessa spinifera*), from Mar to early Jun, with fish predominating through rest of breeding season, primarily sandeels (*Ammodytes hexapterus*) supplemented by herring (*Clupea harengus*), capelin (*Mallotus villosus*), shiner perch (*Cymatogaster aggregata*) and small quantities of other Osmeridae, Scorpaenidae and Stichaeidae; autumn and winter diet poorly known, but crustaceans probably dominate through winter, with fish (including rockfish, herring, sandeels) of secondary importance. Chick fed almost exclusively fish, principally sandeels, sometimes herring, capelin and anchovy; 1-8 meals/day (mean 3·2), mostly at low-light dawn and dusk periods. Food usually obtained singly or in pairs, rarely in groups, usually close to breeding site (up to 10 km offshore) in shallow waters at depths of less than 30 m.

Breeding. Breeding season longer and less synchronous than in other alcid species, with laying and incubation in North America from late Mar to late Aug, and chick-rearing from late Apr to 3rd week Sept; breeding season length increases N to S, c. 110 days in Alaska to c. 180 days in California. Probably monogamous, with high breeding site and mate fidelity. Non-colonial; single pairs at low density in mature forests. Usually lays on platform of moss- and lichen-covered branches or limbs of old-growth conifers at variable heights in lower canopy, less frequently (under 5%) on ground; infrequently on bare ground in tundra regions, usually on inland slopes. 1 egg; incubation 27-30 days, by both sexes for 24-hour periods, with change-overs immediately before sunrise, rarely at dusk; downy chick yellowish with dark brown-black spots above, pale grey on belly, 33 g, semi-precocial; chick-rearing period 27-40 days, with parental care and feeding by both sexes until fledging, when chick flies directly from nest to sea unaccompanied. Breeding success relatively low, c. 30%, with unusually high chick mortality. Survival rates, longevity, and age of first breeding unknown.

Movements. Seasonal post-breeding movements poorly known. Most birds move from exposed coasts into sheltered productive inshore waters, usually near breeding area, where they often occur in large aggregations. Important wintering areas include Kodiak Archipelago, Strait of Georgia, E Puget Sound and Grays Harbor channel; little known of movements or winter concentrations along coastal Oregon and California. Russian population appears more migratory, deserting breeding areas in Sept and Oct, moving into S parts of Sea of Okhotsk during winter; some may overwinter off Sakhalin, but most migrate S to Japan (Hokkaido, Honshu), returning to breeding sites early to late May.

Status and Conservation. Not globally threatened. Currently considered near-threatened. Total breeding populations estimated at c. 300,000 individuals in North America, 85% of which along coasts of Gulf of Alaska and in Prince William Sound, and probably 50,000-100,000 birds in E Russia (based on limited quantitative at-sea observations). Most serious threat is rapid removal of old-growth forest habitat throughout breeding range; also known to incur substantial mortality at sea by drowning in gill-nets and from oil pollution. Population size small and vulnerable, with declines recorded or suspected throughout range (presently c. 3-5% per annum in Alaska and British Columbia), with possible 50% decrease in Alaska in period 1972-1992. Cumulative effects of logging of breeding habitat, gill-netting and oil pollution probably prime causes of reduction; impact of declining forage-fish populations in Gulf of Alaska and elsewhere may also be involved. Forming of large aggregations during winter, often in regions with high oil-tanker traffic, places species at considerable risk. Management plans proposed by Marbled Murrelet Conservation Assessment Core Team must be implemented immediately in order to: ensure adequate nesting habitat; eliminate human activities responsible for current high adult mortality; and minimize loss of nest contents to predators.

9. Kittlitz's Murrelet

Brachyramphus brevirostris

French: Guillemot de Kittlitz **German**: Kurzschnabelalk **Spanish**: Mérgulo Piquicorto
Other common names: Short-billed Murrelet

Taxonomy. *Uria brevirostris* Vigors, 1829, San Blas, Mexico; error = North Pacific.
Monotypic.

Distribution. Bering Sea coasts N into Chukchi Sea and S to Gulf of Alaska: in Russia probably limited to E Chukotskiy Peninsula in Chukchi Sea W to Cape Schmidta and S to Anadyr Gulf, as well as Shelekhov Bay in N Sea of Okhotsk; in Alaska from just E of Cape Lisburne S to Aleutians and E to Glacier Bay and Stileine R (Gulf of Alaska). Winters mainly offshore near breeding area, from E Siberia and Kuril Is S to N Japan (Hokkaido), and from Aleutians E to Glacier Bay.

Descriptive notes. 22-23 cm; 224 g. Small alcid with short brownish bill, and darkish brown iris; brown to darkish brown upperparts mottled buff and white (cryptic sandy brown), merging into largely white belly; dark brown to black tail, with outer edges of feathers white; legs and feet brownish. In winter, largely blackish grey above, with black cap which ends well above eye (unlike *B. marmoratus*); white-fringed scapulars; face, throat and underparts mainly white, with dark patch in front of eye. Juvenile similar to winter adult, but with fine barring on face, neck, underparts and tail.

Habitat. Neritic, usually along rocky sea coasts. In summer, associated with coastal (sometimes inland) mountains and slopes in alpine tundra, glaciers and glacial moraines, breeding on mountain scree slopes, often 0·5-75 km (average c. 16 km) from coast. Winter habitats poorly known, but species thought to winter usually offshore from S parts of breeding range, particularly over banks and along coasts from SE Siberia S to Kuril Is and in SE Alaska.

Food and Feeding. In summer feeds primarily on sandeels (*Ammodytes hexapterus*), capelin (*Mallotus villosus*), herring (*Clupea harengus*), smelt (Osmeridae) and Pacific sandfish (*Trichodon trichodon*), supplemented by euphausiids, gammarid amphipods, and shrimps. Chick diet unknown, probably similar to that of adult in summer. Food habits in winter poorly known, probably planktonic crustaceans and small fish; displays patchy distribution, and concentrates in large flocks of up to 500 birds at food-rich locations, e.g. gatherings over Fairweather Bank (SE Alaska) in Apr totalling 1000's of birds. In summer, forages mainly inshore, in bays and inlets, often concentrated at glacier outfalls and heads of fjords; in Chukchi Sea, up to c. 60 km offshore once ice recedes.

Breeding. Information extremely limited, only 22 nests known (1995). Timing of breeding varies markedly through range, with start of laying c. 1 month later at northernmost locations than those in S: mid-May to mid-Jun in SE Alaska, late May to mid-Jun in S coastal Alaska, early to mid-Jun in Aleutians and Sea of Okhotsk, mid-Jun in Bering Sea, and mid-Jun to late Jun in Chukchi Sea; fledging from mid-Jul to early Aug (SE Alaska) to mid-Aug (Chukchi Sea). Probably monogamous, with behaviour and reproductive patterns similar to *B. marmoratus*; site fidelity possibly high, mate retention unknown. Non-colonial; usually isolated pairs at low densities on unvegetated mountain scree slopes, often at high elevations (mean 570 m). Lays on rock ledge, in crevice, or usually in depression on bare gravelly substrate at base of moderately sized rock (0·3-0·5 m diameter), near top of ridge or summit. 1 egg; incubation period unknown, probably c. 30 days; downy chick buffy-yellow with black spotting above, grey breast and pale grey belly, semi-precocial; chick-rearing 24 days (only 1 record), with both parents at nest delivering food; most fledglings fly directly from breeding site to sea, with post-fledging parental care unlikely. Productivity, survival rates and age of first breeding unknown.

Movements. Post-breeding dispersal into bays and fjords of Prince William Sound occurs late Jul and Aug. Migratory movements limited, most birds in Bering Sea and E Pacific remaining within breeding range; only small numbers from N regions (Chukchi Sea, N Bering Sea) move SW past Kamchatka Peninsula to N Kuril Is and SE to Gulf of Alaska, with few stragglers to N Japan and California. Winter distribution poorly known, but spring influx and initiation of breeding in Chukchi Sea area by mid-Jun is c. 4 weeks later than at S & SE Alaskan coastal locations; some birds push N in leads in ice by late Apr, most later, but normally on site and displaying at Cape Lisburne by Jun.

Status and Conservation. Not globally threatened. Total population size poorly known, but believed to be much smaller than that of *B. marmoratus* (based on summer pelagic count statistics); probably 30,000-130,000 birds, of which at least 70% in Alaska. Information on present status very limited, though small population size alone makes species highly vulnerable to marine pollution and activities of commercial fisheries. Alaskan numbers believed relatively stable up to early 1980's (based upon qualitative indicators), uncertain thereafter owing to possibility of significant mortality from oil spills (Exxon Valdez), commercial gill-net fisheries, and offshore oil developments. Threats at sea similar to those for *B. marmoratus*. Much additional research and survey effort required, particularly along W Pacific coast, to delineate breeding range in NE Russia, and during autumn and winter to identify biological "hot spots". Census methods need to be developed and a monitoring system established to assess population trends throughout range, as well as a major study programme to determine species' basic ecological characteristics and requirements.

PLATE 60

inches 5
cm 13

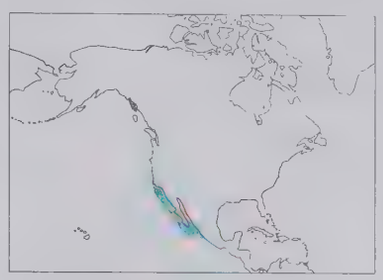
Genus *SYNTHLIBORAMPHUS* M. Brandt, 1837

10. Xantus's Murrelet

Synthliboramphus hypoleucus

French: Guillemot de Xantus **German**: Lummenalk **Spanish**: Mérgulo Californiano Aliclaro
Other common names: Scripps's Murrelet (*scrippsi*)

Taxonomy. *Brachyramphus hypoleucus* Xántus de Vesey, 1860, Cape San Lucas, Baja California.
Sometimes placed in *Brachyramphus*. Both races sympatric with closely related *S. craveri* at San Benito Is (Baja California), where further study required to determine degree of mixing and gene exchange; may be conspecific with *S. craveri*. Race *scrippsi* sometimes considered a separate species. Two subspecies recognized.
Subspecies and Distribution.
S. h. scrippsi Green & Arnold, 1939 - S Californian Channel Is and islands off W coast of Baja California S to at least San Benito Is.
S. h. hypoleucus (Xántus de Vesey, 1860) - NW Baja California (San Benito Is, Guadalupe I); status uncertain on Santa Barbara I, Channel Is, in S California.
Winters from area of breeding colonies N up Pacific coast to S British Columbia and S to S tip of Baja California, mainly inshore.



Descriptive notes. 23-25 cm; mean 148-167 g (130-215 g); wingspan c. 40 cm. Small auk with short, slender black bill; black upperparts with faint greyish cast, including top of head, neck, back, wings and tail; prominent white crescents above and below eye, meeting white of throat; mostly snowy white underparts, with flanks varying from white to mottled grey and white; legs and feet bluish grey, with black webs and claws. Female usually significantly larger than male in culmen, wing chord and weight (averages 11 g heavier), but not bill depth or tarsus length. In winter, often paler greyish black above due to feather wear. Juvenile similar to adult, but with scattered dark barring along flanks. Race *scrippsi* differs in having eye-crescents only very indistinct; suspected clinal variation in bill size, shorter and deeper in N.
Habitat. Offshore and along sea coasts, occupying warmer waters than all alcids except *S. craveri*. Breeds on steep sea cliffs, slopes and canyons on islands. Winters primarily well offshore, with most of population in warm pelagic waters of California Current (14-16°C, off Washington and Oregon), rarely seen inshore where colder waters occur; major concentrations found 20-100 km offshore, usually over deep water, though regularly in small numbers up to 200 km offshore. Pelagic distribution probably determined by relative abundance of small pelagic schooling fish.
Food and Feeding. Mainly larval fish and other small prey. During breeding, mainly larval fish, especially northern anchovies (*Engraulis mordax*) on Santa Barbara I, and also Pacific saury (*Cololabis saira*) and rockfish (*Sebastes*); also sandeels (*Ammodytes*) and crustaceans. Feeds usually within 2-14 km of colony island, with highest numbers over shelf waters (40-100 m deep). Chicks precocial, not fed at nest but fed at sea; diet unknown, likely small fish similar to those eaten by adults. In non-breeding season, occurs in warm waters in association with schooling fish, especially Pacific saury and albacore tuna (*Thunnus alalunga*).
Breeding. Appears on sea near colonies mid- to late Dec, first landing mid-Feb, c. 3 weeks before first laying. Nocturnal at colony; laying asynchronous and variable between years, late Feb to mid-Jun, usual peak from late Mar to mid-Apr (Santa Barbara I), slightly later farther S (Guadalupe I); most hatching late Apr to mid-May. Probably monogamous, with high mate and nest-site fidelity. Breeds mostly in small colonies and at low densities, possibly determined by patchy distribution of suitable nesting habitat: rock crevices, caves, burrows and shrubs. Lays in back of small (usually under 1 m long) dark cave or crevice in cliff, or under boulder, rarely at shallow depth or exposed; sometimes on bare ground under dense vegetation, especially on maritime sandy slopes. 2 eggs, with laying interval 8 days (5-12); incubation from 2nd egg, averages 34 days (27-44), by both sexes equally with shifts averaging 3 days (1-6); hatching synchronous; downy chick c. 25 g, black above and white below (adult pattern), with foot almost as large as adult's; chick mobile soon after hatching, brooded but not fed for 1-2 days, then taken by parents at night to sea, where family immediately swims away from colony, often 10 km or more offshore; young can undergo partial hypothermia during at least 1st week of life, but details of parental care at sea and time to independence not known. Breeding effort and performance lower when anchovy abundance low. Nesting success (nests fledging at least 1 young) averaged 57% (27-75%) at Santa Barbara I (1983-1993), with annual productivity 0·72 chicks fledged/clutch (0·3-1·36). Prime cause of egg loss is predation by deer mice (*Peromyscus maniculatus*). Survival and age of first breeding unknown, probably similar to congeners.
Movements. Post-breeding dispersal from nesting islands Apr or May (sometimes late Mar or Jul), largely offshore to W, and to N; individual pairs and their flightless offspring swim on water. Movement to wintering areas probably slow, with arrival Jun to early Jul (peak numbers Jul-Aug) off C Californian coast, where large numbers remain on outer continental shelf and fewer in similar habitats N to Washington and S British Columbia until late Nov or early Dec. Return to breeding locations probably Nov-Jan.
Status and Conservation. Not globally threatened. Currently considered near-threatened, but probably merits Vulnerable status. Total population c. 5600 breeding birds, concentrated at 4 major colonies: Santa Barbara I (1500) and Los Coronados (750) in S California and N Baja California, and San Benito (c. 1000) and Guadalupe (2400-3500) farther S. Population has undergone marked declines, including numerous colony extinctions, largely due to introduced predators such as black rats (*Rattus rattus*) and feral cats. Limited breeding range and concentration of remnant population at only a few colonies make species highly vulnerable to other human activity, including: oil pollution, as Santa Barbara colony is 80-100 km from offshore oil wells and within 20 km of major Los Angeles oil-tanker lane, indeed oil spills from either source could easily extirpate species from S California Bight; commercial fisheries, with drowning in offshore drift gill-nets; disturbance at nesting grounds, with high desertion rate noted during laying and incubation; and possible chemical poisoning. Immediate management needs are: control and eradication of introduced predators on extant and recently extirpated breeding islands; careful regulation of tourism on islands of Baja California; expanded fisheries observer programmes for better assessment of impact of gill-net fisheries; and establishment of system of protection of all major colonies, and monitoring programme to measure population size and status with precision.
Bibliography. Bancroft (1930), Bent (1919), Boswall (1978), Briggs, Tyler, Lewis & Carlson (1987), Briggs, Tyler, Lewis & Dettman (1983), Carter *et al.* (1992), Collins (1979), Cowan & Martin (1954), Drost & Lewis (1995), Eppley (1984), Everett & Anderson (1991), Feinstein (1958), Howell & Webb (1995a), Hunt & Butler (1980), Hunt, Pitman *et al.* (1981), Jehl (1984), Jehl & Bond (1975), Jehl & Everett (1985), Manuwal (1984), Murray (1980), Murray, Winnett-Murray, Eppley *et al.* (1983), Murray, Winnett-Murray & Hunt (1980), Page *et al.* (1990), Scott *et al.* (1971), Sealy (1975c), Sowls *et al.* (1980), Springer *et al.* (1993), Wilbur (1987).

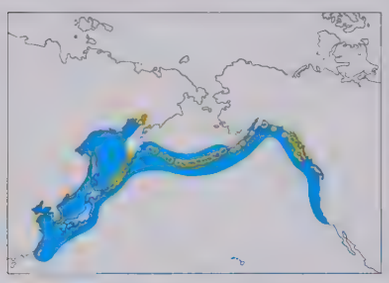
11. Craveri's Murrelet

Synthliboramphus craveri

French: Guillemot de Craveri **German**: Craverialk **Spanish**: Mérgulo Californiano Alioscuro

Taxonomy. *Uria Craveri* Salvadori, 1865, Raza Island, Gulf of California.
Sometimes placed in *Brachyramphus*. May be conspecific with *S. hypoleucus*, but little evidence of hybridization in San Benito Is, where both breed. Monotypic.
Distribution. Numerous islands in Gulf of California (N to Consag Rock), and probably islands along Pacific coast of Baja California N to San Benito. Winters at sea in Gulf of California and along coasts N to S California (Monterey Bay) and S to Sonora.

Descriptive notes. c. 21 cm; 128-149 g. Small alcid with short, slender black bill; brownish black upperparts, with black cap extending to bottom edge of lower mandible; white throat and lower sides of face; white underparts, with narrow black wedge on side of breast, and blackish on flanks extending back over body; legs and feet bluish grey, with black claws. Bill slightly longer, but less robust, than in *S. hypoleucus*; black of cap reaches farther below eye and extends to bottom of lower mandible; more elongated black patch on side of breast, and darker dusky grey underwing-coverts. No seasonal variation. Juvenile similar, but with slightly shorter bill, darker upperparts, and fine blackish bars or spots on sides of breast and belly.
Habitat. Offshore and along sea coasts; has southernmost and most restricted range of any alcid, and occupies warmest waters. Breeds on steep sea cliffs and maritime slopes of islands. In winter, occurs mostly offshore close or adjacent to breeding range, often at considerable distances from shore in relatively warm pelagic waters of California Current (probably similar to S winter population of *S. hypoleucus*).
Food and Feeding. Studies lacking, but limited collections during nesting period and early post-breeding dispersal indicate mainly small-sized larval fish (largest 40-70 mm), especially rockfish (*Sebastes*), herring (Clupeidae) and lanternfish (*Benthosema panamense*), but also small Pacific mackerel (*Scomber japonicus*), shrimps and squid; northern anchovy (*Engraulis mordax*) and Pacific saury (*Cololabis saira*) may also be important. Appears to forage in pairs or alone, often in small groups widely scattered, rarely associated with other seabird species. Probably feeds relatively close to colony during nesting season, at or near surface over deep water. Precocial young taken to sea at 1-2 days and fed small pelagic fish.
Breeding. Appears in waters off breeding sites in late Dec and Jan, occupying sites early Feb; peak laying 2nd half of Feb and early Mar, but breeding synchrony low, and nesting period extends to early Apr; most families depart Apr to early May. Mating system poorly known; probably monogamous, with high mate and site fidelity. Nests in small groups at low density, largely determined by availability of suitable sites; nocturnal at colony. Lays usually in scrape on bare rock or soft substrate at end of rock cavity or crevice, but also in ground burrows, under dense shrubs and boulders. 2 eggs; incubation from 2nd egg, probably averages 31-33 days, shared by both sexes equally; hatching synchronous; downy chick c. 25 g, mostly dark brown-black above and white below (adult pattern, including sooty underwing), precocial and mobile, not fed at nest, which abandoned after 1-2 days when entire family goes to sea at night; family undertakes migration by swimming away from colony; parents protect and feed chicks at sea, but time to independence not known. Nesting success probably variable, sometimes high (75%), though chick survival during first month at sea appears low (30-35%). Most egg losses due to introduced predators (small rodents). Survival rates, recruitment and age of first breeding unknown.
Movements. Post-breeding dispersal begins Jun-Jul; most birds remain within breeding range, with general movement N in Aug-Oct off Pacific Baja California N to S California (Monterey) and some S to Sonora (W Mexico), and offshore W to Guadalupe I. Numbers increase in Gulf of California during Dec-Jan, with reoccupation of breeding sites starting early Feb. Pelagic distribution during autumn and winter uncertain due to confusion with *S. hypoleucus*.
Status and Conservation. Not globally threatened. Currently considered near-threatened, but probably merits Vulnerable status. Total population estimated at 6000-10,000 breeding birds, with 90% at 3 locations (Partida, Rasa, Tiburón) in Gulf of California, and remainder scattered elsewhere in Gulf and on Pacific coast of Baja California. Population small and extremely vulnerable to human activities during and outside breeding season. Major threats are: disturbance at breeding locations, including introduced predators (mice, rats, cats), human disturbance (predation, tourism developments) and habitat alteration; and disturbance at sea, including commercial fisheries (competition for food, drowning in gill-nets), oil spills from offshore drilling and tanker traffic, and chronic disturbance caused by increase in ship traffic in Gulf of California. Population known to have declined recently, with several colonies extirpated and others severely reduced and threatened (e.g. Tiburón), mostly by introduced predators. Management needs similar to those for *S. hypoleucus*; immediate conservation action required.
Bibliography. Anderson (1983), Anderson *et al.* (1976), Anon. (1983a), Bancroft (1930), Bent (1919), Breese *et al.* (1993), DeWeese & Anderson (1976), Dunning (1984), Everett & Anderson (1991), Howell & Webb (1995a), Hunt, Pitman *et al.* (1981), Jehl (1984), Jehl & Bond (1975), Johnsgard (1987), Manuwal (1984), Springer *et al.* (1993), Velarde & Anderson (1994), Velarde *et al.* (1985), Violani & Boano (1990), Wilbur (1987).



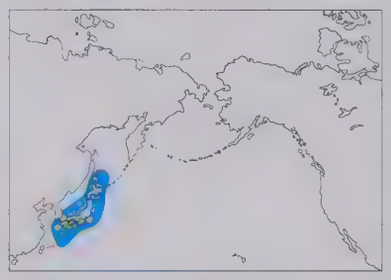
12. Ancient Murrelet

Synthliboramphus antiquus

French: Guillemot à cou blanc **German**: Silberalk **Spanish**: Mérgulo Antiguo
Other common names: Black-throated/Grey-headed Murrelet

On following pages: 13. Japanese Murrelet (*Synthliboramphus wumizusume*); 14. Cassin's Auklet (*Ptychoramphus aleuticus*); 15. Parakeet Auklet (*Cyclorrhynchus psittacula*); 16. Crested Auklet (*Aethia cristatella*); 17. Whiskered Auklet (*Aethia pygmaea*); 18. Least Auklet (*Aethia pusilla*); 19. Rhinoceros Auklet (*Cerorhinca monocerata*); 20. Atlantic Puffin (*Fratercula arctica*); 21. Horned Puffin (*Fratercula corniculata*); 22. Tufted Puffin (*Fratercula cirrhata*).

Taxonomy. *Alca antiqua* Gmelin, 1789, Bering Sea.
Racial subdivision recently revived, and requires additional examination. Two subspecies provisionally recognized.
Subspecies and Distribution.
S. a. antiquus (Gmelin, 1789) - Yellow Sea and Sea of Japan (Peter the Great Bay) N through Sakhalin, Kuril Is and N Sea of Okhotsk (Talan I) to Kamchatka, then E through Aleutians to S Alaska (St Lazaria I, Forrester I, Kodiak I, Semidi Is, Shumigan Is, Sandman Reefs), and then S to Queen Charlotte Is.
S. a. microrhynchos Stepanyan, 1972 - Mednyi I, Commander Is.
Winters mostly offshore on continental shelf, with widespread distribution from Pribilofs and Aleutians S to Taiwan, and in America S regularly to N California, rarely to N Baja California.



Descriptive notes. 24-27 cm; c. 206 g (177-249 g). Small, stocky alcid; thick, rather short horn-coloured bill with blackish culmen; dark brown iris; black head, nape and throat, with white stripe (filamentous plumes) over eye to nape; bluish grey upperparts; snowy white underparts, with greyish brown line separating underwing and belly; legs and feet pale pinkish grey, with dusky joints and blackish webs. Separated from *S. hypoleucus*, S. craveri, *Brachyramphus marmoratus* and *Ptychoramphus aleuticus* by contrasting black throat bib. In winter, lacks white head plumes, has less or no black on throat, and white from underparts extends high up on sides of neck. Juvenile similar to winter adult, but bill darker, shorter and less robust, and black of head extends down only to gape, not to chin and lower face as in adult. Race *microrhynchos* said to have smaller bill and less speckling on side of neck.
Habitat. Offshore and along rocky sea coasts. Breeds on islands, often with dense vegetation of trees, shrubs and grassy hummocks, normally on soft slopes, sometimes near trees or rocks; often in association with other alcids. Forages mainly in offshore waters to edge of continental shelf, but sometimes inshore where oceanographic processes (e.g. tidal upwellings) concentrate food near sea surface. Winters well offshore, often off the shelf break, but also inshore in regions of strong tidal currents and upwellings. Distribution determined largely by concentrations of planktonic crustaceans and small fish.
Food and Feeding. During early nesting in British Columbia mostly planktonic crustaceans, especially euphausiids (mainly *Thysanoessa spinifera*, with smaller numbers of *T. pacifica*), small larval fish later comprising juvenile sandeels (*Ammodytes hexapterus*), shiner perch (*Cymatogaster aggregata*), and rockfish (*Sebastes*). Diets similar elsewhere, largely mixed crustaceans and fish: in Gulf of Alaska, euphausiid *T. inermis* dominant, with lesser amounts of fish, i.e. capelin (*Mallotus villosus*) and walleye pollock (*Theragra chalcogramma*); in Sea of Okhotsk, crangonid shrimps (*Sabinea*, *Sclerocrangon*) and sandeels, rainbow smelt (*Osmerus mordax*) and sculpin (*Triglops*) dominated; in Peter the Great Bay (Sea of Japan), some chicks fed Pacific herring (*Clupea harengus*), Pacific saury (*Hypoptychus dybowskii*) and small cancroids. Variation in diet due to intraseasonal changes in available prey and differences in prey types between water types and systems. Winter diets poorly known, but mainly *Euphausia pacifica* (12-24 mm long) off Vancouver I (British Columbia), varying from 30% in Nov (60% *Clupea harengus*) and 82% in Dec to 92% in Jan and 100% in Feb. Forages mainly over continental shelf and shelf breaks, usually in small flocks sometimes up to 50 birds, rarely solitarily. Diving times under 45 seconds, indicating depths of c. 10-20 m.
Breeding. Arrives in vicinity of colonies a month before laying, with first landing c. 2-3 weeks before first egg laid; median clutch completion mid-Apr to early May in British Columbia, end Apr to mid-May in SE Alaska, first half Jun in Aleutians, and from mid-Mar in China to late Jun or early Jul in Sea of Okhotsk and Kamchatka; most hatching late May to mid-Jul. Probably monogamous, with mate and site fidelity high; no definite divorces recorded. Colonial, at relatively low densities (under 1 pair/10 m² in British Columbia), often in association with other alcids, e.g. *Ptychoramphus aleuticus* and *Cerorhinca monocerata* (British Columbia), and *Aethia* auklets, *Fratercula corniculata* and *F. cirrhata* (Alaska). Nocturnal at colony. Nests primarily in burrows excavated in soil, but also in rock crevices and cavities, occasionally in holes dug by other subterranean nesters, usually on slopes less than 300 m from sea. Lays at night in nest chamber at end of short burrow (60-150 cm, rarely 2 m), in scrape lined with grass, leaves and twigs; laying fairly synchronous, usually spanning c. 45 days, with 50% of clutches initiated within 10 days. 2 eggs, laying interval 7-8 days (6-10); incubation averages 32-33 days (29-37), by both sexes equally in shifts usually lasting c. 3 days (1-6); hatching synchronous, usually within 2-3 hours, occasionally up to 36 hours; downy chick mostly bluish grey on back with black head, white below, c. 33 g, precocial and mobile; chicks remain in burrow unfed for 1-3 (maximum 4) days before departing for sea usually with both parents at night, and family immediately swims away, often 40-50 km from colony within 12-20 hours of departure; parents guard and feed chicks until fully grown, at least 4-5 weeks. Hatching success normally high (c. 96%) at undisturbed nests, with c. 92% of pairs taking 2 chicks to sea; most losses due to desertion, usually before start of incubation, less frequently to predation of eggs and chicks by deer mice (*Peromyscus*). Adult mortality from natural predators such as Bald Eagle (*Haliaeetus leucocephalus*), Peregrine Falcon (*Falco peregrinus*) and Common Raven (*Corvus corax*) can be high, but heaviest predation from introduced rats (*Rattus norvegicus*) and raccoons (*Procyon lotor*). Adult annual survival averages 77%, with estimated life expectancy of breeders c. 4·5 years (Reef I, British Columbia). Age of first breeding 2-4 years.
Movements. Post-breeding dispersal somewhat limited, some birds remaining within breeding range. Rapid exodus from N British Columbia Jul-Sept, with marked S movement in Oct in both W and E Pacific, S to California (arrives late Oct) and to Japan and Korea (high numbers present Dec-Mar). Dispersal generally limited to short distances except in Sea of Okhotsk, where birds forced out by winter ice. Returns to breeding areas at least a month before laying begins. Details of winter distribution and movements are lacking throughout range.
Status and Conservation. Not globally threatened. Total population estimated at 1,500,000 birds (1,000,000-2,000,000). Vulnerable in many areas, and population much reduced throughout breeding range owing largely to introduction of alien mammalian predators, by accident (rats) and from fur-farming (foxes, raccoons). Magnitude of regional declines estimated at c. 50% in Queen Charlotte Is (since early 1960's), 80% in Aleutians (since early 1900's), and probably high throughout Asia from lengthy exposure to human predation and introduced mammals, especially rats; extirpation of small, unprotected populations in Kuril Is and Sea of Japan seems imminent. Other threats include oil pollution (high mortality from oiling in Sea of Japan; vulnerable elsewhere at sea owing to winter concentrations in regions of high tanker traffic) and human disturbance (adverse effects of tourism near colonies and fatal attraction to lights on fishing boats and other craft). Present management needs are: continued programmes to eradicate introduced foxes and rats from both active and former colony sites in British Columbia and Alaska; effective control programme to remove raccoons from key sites in Queen Charlotte Is (urgent requirement to safeguard population in British Columbia, the single most important site for the species); rapid development and implementation of conservation action plans for key islands in W Pacific, by national and international partnerships; and establishment of integrated international monitoring programme to assess population size and status throughout breeding range.

13. Japanese Murrelet

Synthliboramphus wumizusume

French: Guillemot du Japon **German**: Japanalk **Spanish**: Mérgulo Japonés
Other common names: Crested Murrelet

Taxonomy. *Uria wumizusume* Temminck, 1835, Japan.
Monotypic.
Distribution. Coasts and islands off E & S Japan (Izu Is S to Shikoku and Kyushu) and South Korea. Winters mostly offshore from breeding locations.

Descriptive notes. 26 cm; 183 g. Short, thick, pale bluish grey bill with dark culmen; iris dark brown, almost blackish; black head with crest of long, narrow black feathers, and with white stripes on sides from top of eye meeting on nape; blackish and bluish grey upperparts; white throat and underparts, with greyish black flanks; yellowish grey legs and feet. Distinguished from *S. antiquus* by crest and by lack of black on throat. In winter, lacks crest and head stripes; resembles *S. antiquus*. Juvenile as winter adult, but head and upperparts appear browner.
Habitat. Offshore and along sea coasts in boreocool subtropical waters of NW Pacific. Breeds on small rocky islets and sea coasts. Forages mainly offshore, to edge of continental shelf, also inshore where upwellings or converging currents concentrate food near surface. Winters offshore, mostly in temperate, cool subtropical waters.
Food and Feeding. Mostly planktonic crustaceans, especially euphausiids, and small larval fish throughout year. Summer foods probably similar to those of *S. antiquus* in Sea of Japan and S Sea of Okhotsk, mainly crangonid shrimps (*Sabinea*, *Sclerocrangon*) and Pacific herring (*Clupea harengus*), Pacific saury (*Hypoptychus dybowskii*), sandeels (*Ammodytes*), smelt (*Osmerus*) and sculpin (*Triglops*). Winter diet unknown, probably largely euphausiids. Feeds mainly over continental shelf, usually in small groups, with diving times and depths as for *S. antiquus*.
Breeding. Phenology and reproductive biology poorly known. Spring arrival mid- to late Feb; laying normally mid-Mar to late Jun or early Jul, and fledging mostly by late Apr to end of May. Probably monogamous, with high mate and site fidelity. Colonial, in small and localized groups owing to small population size. Nocturnal at colony. Nests primarily in rock crevices and cavities and under boulders, but also excavates short burrows in soil and under roots of trees and tussock grasses, sometimes in debris and stone walls; may use existing burrow of other species. 2 eggs, sometimes 1, laid at night, laying interval probably 7-8 days; incubation period unknown, probably c. 32-33 days, by both sexes for periods of 24-72 hours; hatching synchronous, within a few hours; downy chick brownish grey above, white below, precocial, unfed until leaving at night with parents for sea, c. 1-2 days after hatching, when family immediately swims offshore, often travelling non-stop for 10-20 hours; parents guard and feed young until fully grown, probably at least 1 month later. Breeding success relatively low, c. 38% of eggs laid produce chicks that go to sea. Most losses at egg stage, occasionally young chicks, usually taken by introduced predators e.g. rats (*Rattus*) and other small rodents when left unattended. Survival rates and age of first breeding unknown; probably as for *S. antiquus*.
Movements. Winters mainly offshore, mostly close to breeding areas. General post-breeding dispersal normally within warm currents flowing NE off E coast (Kuroshio Current) and W coast (Tsushima Current) of Kyushu and Honshu; birds reported N to S Sakhalin and Kuril Is and S to Taiwan. Most return to vicinity of colonies by mid- to late Feb, reoccupying nesting sites shortly thereafter. Movements between post-breeding exodus and spring return comprise short distances. Winter distribution poorly known, but likely determined by relative abundance of small fish and planktonic crustaceans.
Status and Conservation. VULNERABLE. Rarest and most threatened alcid, and probably second-most threatened seabird species in N Hemisphere. Population small, estimated at c. 5000-6000 birds (1995), restricted to 5 small areas off SE Japan: Izu Is, with c. 1670+ birds at 8 sites; Honshu, with 200+ at Mimiana I and small numbers at Kutsujima and Nanatsujima in Sea of Japan; Shikoku, with small numbers on Koshima I; Kyushu, with 3000 at Biro I, 60 at Eboshi I, and 30 at Okinoshima Is; and Danjo Is, with small numbers at 2 sites. Minute population of under 10 pairs reported in South Korea; may also nest in very small numbers (under 100 birds) in Peter the Great Bay, but fledglings and adults collected at sea in region may have migrated there from Japanese colonies. Small population concentrated at only a few locations during and outside breeding season makes species highly vulnerable to disturbance from human activities. Historically, believed to be more widespread and numerous, but human exploitation for food, habitat destruction and alteration, and introduction of alien predators to breeding colonies have undoubtedly caused extirpation of many island populations. In Izu archipelago, once considered the stronghold of the species, current total is under 2000 birds, with breeding at only 3 of 10 islands that had active populations in early 1950's. Rats and feral cats continue to be the major threat. Immediate conservation need for species' survival is protection of existing breeding sites by: regulation and control of human activity; initiation of programme to eradicate all alien predators at active and former colonies; establishment of control measures to prevent spread of alien predators to predator-free islands; and a comprehensive survey and monitoring programme to determine present distribution and numbers, assess population trends, and identify factors responsible for changes observed. Highest priority must be given to this conservation goal by national and international agencies responsible for protection and management of marine birds and their habitats.

Genus *PTYCHORAMPHUS* M. Brandt, 1837

14. **Cassin's Auklet**

Ptychoramphus aleuticus

French: Starique de Cassin **German**: Aleutenalk **Spanish**: Mérgulo Sombrío
Other common names: Aleutian Auk

Taxonomy. *Uria Aleutica* Pallas, 1811, north Pacific Ocean.
Apparent racial variation may be clinal. Two subspecies provisionally recognized.
Subspecies and Distribution.
P. a. aleuticus (Pallas, 1811) - Aleutian Is to SW & SE Alaska, then S to N Baja California (San Geronimo, San Martin and Guadalupe Is).
P. a. australis van Rossem, 1939 - W Baja California from San Benito Is S to Asuncion and San Roque Is.
Winters within breeding range, mostly offshore, from S British Columbia to S Baja California, with some N to SE Alaska.

Descriptive notes. 23 cm; 150-200 g. Small, plump alcid; short blackish grey bill with base of lower mandible yellowish; white iris; dark greyish brown head, fading to paler brown chin and throat; white crescent above eye; blackish to slate grey upperparts; greyish brown breast and flanks, white belly; legs and feet bluish pink, with black claws. No marked seasonal variation. Juvenile has whiter throat, browner wings and tail, and dark brown iris. Races nearly identical, with *australis* smaller in linear measurements and mass.
Habitat. Offshore and along sea coasts, mostly over continental shelf to edge, but often beyond into deep ocean. Breeds on coastal islands, with or without trees, using wide range of nesting habitat from steep rocky sea cliffs and slopes to flattish ground. Mostly offshore in winter, sometimes remaining inshore near colony sites, particularly in S of range. Utilizes coastal upwellings in spring and summer, and these probably important throughout year, but winter ecology poorly known.
Food and Feeding. Mostly crustaceans throughout year, supplemented by other invertebrates and small larval fish. Quantitative information largely restricted to chick diet during summer: mainly copepods (*Neocalanus cristatus*) and euphausiids (*Thysanoessa spinifera*, *T. longipes*) in British Columbia; *T. spinifera*, amphipods (*Phromema*) and squid (*Loligo opalescens*) in N California, and diet similar in C California (Farallon Is) but also some fish, mainly rockfish (*Sebastes*) and larval sanddab (*Citharichthys*); diet in other regions unknown. Chicks fed 1-2 meals/day, each averaging 17-25 g of mostly crustaceans; adults bring in food at night, carried in specialized sublingual gular pouch. Often forages in small groups, occasionally large aggregations but rarely alone, both day and night, probably at considerable distances (over 50 km) from colony. Dives average 42 seconds, to depths of 20-80 m.
Breeding. Arrival at colony and start of laying vary greatly with latitude, due largely to differences in oceanographic conditions; nests late Nov to Apr in Baja California; elsewhere, laying period earliest and longest in S of range, in C California (Farallon Is) generally from early Mar to late Apr, rarely to late May; later farther N, normally mid-Apr to late May in British Columbia and early Jun to early Jul in Alaska (Sanak I). Only alcid species known to produce 2 broods in single breeding season, reported only for Farallon Is, with median dates of 2nd clutch mid-Jun to early Jul, c. 90 days after 1st clutch. Monogamous, with high mate and site fidelity. Highly colonial, in small to immense aggregations (under 500 to 1,100,000 birds), usually at high densities (0·7-1·1 pairs/m²) on optimal maritime grassy slopes, lower on inland flattish bare ground or with shrubs and trees (less than 0·2 pairs/m²); nocturnal at colonies. Nest placed in crevice, cavity, cave or hole, or in burrow (c. 1 m long) dug into soft soil; lays on rough scrape on bare chamber floor, occasionally lined with bits of vegetation. 1 egg; incubation averages 38-39 days (37-57), by both sexes; early egg losses replaced after c. 17 days (9-25); downy chick black to darkish grey above, grey to pale grey below, c. 18 g, semi-precocial; chick-rearing averages 43 days (41-50), with feeding by both parents only at night, fledgling departing to sea alone, mostly before dawn, just under adult size. Annual variation in breeding success relatively low, except in unusually warm-water years, normally 60-65% of eggs laid produce fledglings (C California, British Columbia); strongly influenced (positively) by occurrence of cold-water upwellings near colonies. Most egg and chick losses due to removal by gulls from short burrows or crevices, also by introduced rats (*Rattus*) and foxes (*Alopex lagopus*, *Vulpes vulpes*) at some colonies. Adult annual survival 86%; estimated survival of fledglings to breeding age c. 65%. Age of first breeding usually 3 years, sometimes 2 or 4.
Movements. Winters mainly offshore within breeding range. S populations relatively sedentary, staying at sea in vicinity of colonies, often visiting colony at night in any month; birds from Alaska and British Columbia migratory, moving S along coast as far as California, where build-up of 500,000-1,000,000 birds occurs during autumn, numbers far exceeding total population from Washington to Baja California. Exodus from wintering areas begins as early as Dec, mostly later during Jan-Feb, with birds reaching N parts of range during Mar-Apr. In general, dispersal patterns and timing of spring influx and autumn exodus require additional study. Distribution largely determined by abundance of small crustaceans, squid and fish.
Status and Conservation. Not globally threatened. Population sizes and trends relatively well known, though distribution and estimates of Alaskan and Mexican populations incomplete. Estimated total population at least 3,600,000 breeding birds, with centre of abundance in British Columbia. Regional totals of c. 600,000 birds in Alaska, with 100,000 on Nigrud Is, Umga I and Chagulak; c. 2,700,000 in British Columbia, with 1,095,000 on Triangle I; c. 88,000 in Washington, with 54,600 on Alexander I; 500 in Oregon; c. 131,000 in California, with 105,000 on SE Farallon I; and 20,000-40,000 in Baja California on islands of San Benito, San Geronimo, Asuncion, San Roque. Population formerly much larger in range and size; reduced as result of widespread human activity from at least 19th century through first half of 20th century, particularly from egging and hunting at colonies and introduction of mammalian predators (foxes, rats, cats) and herbivores (goats). Many colonies in Aleutians and Gulf of Alaska extirpated as result of fox-farming industry, as was probably the case too at several locations W of Buldir I (suspected former colonies at Near Is, Commander Is, Kamchatka and Kuril Is). Rats have destroyed large colonies from British Columbia (e.g. Langara I) to extreme S limit of range, as have introduced foxes and cats (e.g. Channel Is, California) and domestic grazers (e.g. goats on Guadalupe I). Natural factors also important; population declines reported due to increases in Bald Eagles (*Haliaeetus leucocephalus*) and Peregrine Falcons (*Falco peregrinus*) in British Columbia and Washington, and Western Gulls (*Larus occidentalis*) in California; both decreases and increases in N California (e.g. Farallon Is) at least partially explained by intrusion and withdrawal of anomalous warm-water conditions. Overall, introduced mammals (foxes, rats, cats, goats) remain the most serious threat, followed by oil pollution at sea, commercial fisheries, habitat destruction, and colony disturbance (tourism developments and research). Immediate management actions required include: protection of large and small colonies from direct human disturbance; initiation of control programmes to eradicate introduced predators and remove domestic livestock at active and former breeding sites; measures to restore historical populations, particularly in Alaska and Baja California; restrictions on gill-net fishing close to colonies; and continued development of monitoring programmes to assess changes in population size and status in Alaska, Oregon and Baja California.

Genus *CYCLORRHYNCHUS* Kaup, 1829

15. **Parakeet Auklet**

Cyclorrhynchus psittacula

French: Starique perroquet **German**: Rotschnabelalk **Spanish**: Mérgulo Lorito

Taxonomy. *Alca psittacula* Pallas, 1769, Kamchatka.
Monotypic.
Distribution. Chukotskiy Peninsula S to Commander Is, Kamchatka, Sea of Okhotsk (Matykyl I) and Kuril Is, and W Alaska from Diomede Is and Norton Sound S to Aleutians and E to N Gulf of Alaska (Prince William Sound). Winters mostly at sea and along coasts, often at limit of open water near breeding locations, from Bering Sea S to N Japan and casually to S California. General pattern of distribution and limits poorly known.

Descriptive notes. 23-25 cm; 297 g. Short, stubby orangish red bill, deep and laterally compressed, with upturned lower mandible producing circular appearance, yellowish at gape; sooty black head with white nuptial plume extending back from eye, and yellowish white iris; black upperparts and chin and throat; mostly white underparts; legs and feet pale grey, with blackish webs and black claws. Differs from much smaller *Aethia pusilla* in distinctly larger bill and black throat. In winter, bill dull brownish red, facial streak less distinct or absent, and throat white. Juvenile similar to winter adult.
Habitat. Marine, occurring offshore and along rocky sea coasts. Breeds mainly on offshore islands, using steep sea cliffs, rocky talus slopes, often turf-covered (mosses, grasses, herbs), and beach boulder fields, usually in association with other auklet species. Mostly pelagic during winter, some remaining in ice-free regions within breeding range (Aleutians, Pribilofs), but most disperse into N Pacific oceanic boreal waters as far S as Japan and California.
Food and Feeding. During breeding season, feeds mainly on planktonic crustaceans, particularly euphausiids and amphipods early and calanoid copepods during chick-rearing, supplemented with varying amounts of other invertebrates (cephalopods, polychaetes) and small fish; overall, the most diverse diet of all auklets and therefore considered a food generalist. Diet information largely from chick meals (adult summer diet probably similar); major prey (St Lawrence I and Pribilofs) includes hyperiid amphipods (*Parathemisto libellulu*, *P. pacifica*), euphausiids (*Thysanoessa*), copepods (*Neocalanus cristatus*), decapod larvae, Ctenophora, Scyphomedusae, and juvenile fish, mostly sandeels (*Ammodytes hexapterus*) and walleye pollock (*Theragra*). Chick fed 2-4 meals/day, food carried by parents in sublingual throat pouch. Foods usually obtained at considerable distances from colony, sometimes closer on shallow inner shelf and coastal regions. Winter diet not known, probably mostly macrozooplankton. Dives normally under 60 seconds to depths usually above 30 m.
Breeding. Spring arrival and start of laying variable, earliest in S and latest in extreme N, with differences between regions c. 4-5 weeks; normally returns to colonies between Apr and May (St Lawrence I mid-May, Diomede Is late May or sometimes early Jun), with start of laying 3-4 weeks later, May to mid-Jul, but can be delayed in N by late snow-melt; hatching to dispersal usually synchronous, mostly mid-Aug to end Sept. Monogamous, with site fidelity high; mate retention uncertain, probably also high. Small, loose to large colonies, largely determined by availability of suitable nesting sites; usually with other auklets, especially *Aethia cristatella* and *A. pusilla*. Nests deep inside dark crevices and cavities; lays in rough scrape on bare ground, sometimes lined with small pebbles. 1 egg; incubation averages 35-36 days, by both sexes for periods of probably 24 hours (uncertain); replacement of lost eggs rare, but some early losses replaced after 16 days; downy chick blackish brown above, head paler than back, pale brownish grey below, c. 28 g, semi-precocial; chick-rearing averages 35 days (34-37), with care and feeding by both parents until fledging, when chick flies to sea alone at night. Breeding success not well known, but c. 65-68% of eggs laid hatch, and limited studies indicate c. 76% of hatchlings fledge, giving total success of c. 50-51%. Most egg and chick losses due to predation by voles (*Microtus*, *Clethrionomys*); some eggs lost by accidental breakage. Adult and juvenile survival unknown. Age of first breeding estimated at 3 years.

Movements. Migratory movements poorly known. Dispersal from late Aug to early Oct. Some birds overwinter in open waters near breeding locations (Pribilofs, Aleutians), but most birds probably move considerable distances S to winter offshore in oceanic waters of N Pacific, S as far as Japan (Hokkaido, and irregularly to Honshu) and casually to S California. No winter sightings from Gulf of Alaska, few from SE Alaska and British Columbia, and regular records from Washington to California; similar exodus from E Bering Sea, Kamchatka and Sea of Okhotsk S and offshore of Kurils to Japan. Most birds return to colonies Apr-May, late May and early Jun at northernmost sites; arrives Commander Is and Aleutians late Apr, St Lawrence I by mid-May, and Bering Strait (N Chukotskiy, Diomede Is, Seward Peninsula) late May to early Jun. Migratory movements and patterns complex, requiring further study; apparently influenced by fluctuations in surface temperatures and salinities.
Status and Conservation. Not globally threatened. Breeding population sizes and trends only roughly known. Estimated total population c. 1,200,000 individuals, with c. 800,000 (400,000-1,000,000) in W Alaska and c. 400,000 (380,000-500,000) in E Siberia. Centres of abundance: Sea of Okhotsk, with 350,000 birds at 15 colonies, of which 200,000 on Matykyl I (Yamskie Is); E Bering Sea, with 180,000 at Pribilofs and 20,000–40,000 at Diomedes; and NW Gulf of Alaska, with 58,000 at Chowiet I (Semidi Is). Information on breeding numbers incomplete for many regions, particularly along W Bering, Kamchatka and Okhotsk coasts, and at more than 20% of sites in Alaska. Trends unknown throughout breeding range, but abundance of birds and colonies probably much reduced from earlier times by negative impacts of human exploitation for food, fox farming, and other introduced predators (rats, voles, feral cats and dogs) in all regions. Current threats within breeding range come from continued human disturbance and predation, introduced mammalian predators, commercial fisheries and marine pollution (particularly offshore oil developments in Sea of Okhotsk); principal threats in winter include oil fouling at sea (beached birds recorded regularly through winter range) and ingestion of small plastic particles in N Pacific. High priority should be given to: eradication of introduced predators at present and former colonies; establishment of monitoring system to assess population size and status; better understanding of post-breeding distribution and movements, and ecological requirements at sea; and magnitude of mortality associated with oiling, consumption of plastic particles, and drowning in gill-nets. Concentration at only a few locations makes species particularly vulnerable to human activities.

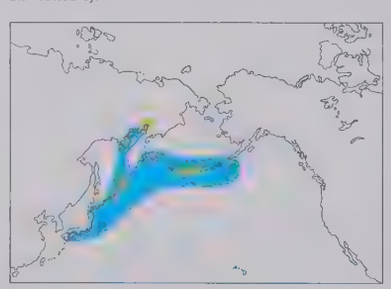
Genus *AETHIA* Merrem, 1788

16. **Crested Auklet**

Aethia cristatella

French: Starique cristatelle **German**: Schopfalk **Spanish**: Mérgulo Empenachado

Taxonomy. *Alca cristatella* Pallas, 1769, Hokkaido to Kamchatka.
Monotypic.
Distribution. Chukotskiy Peninsula S through Diomede Is to N Sea of Okhotsk, Sakhalin and Kuril Is, and W Alaska S through St Lawrence I, St Matthew I and Pribilofs to Aleutians E to Shumagin Is. Winters at sea and along coasts in Bering Sea, often close to breeding areas where open water exists, S to Gulf of Alaska and N Japan; N and S limits poorly known.



Descriptive notes. 18-20 cm; c. 260 g; wingspan 40-50 cm. Distinctive forward-coiled ornamental facial plumes and crest, striking bright reddish orange and yellow-tipped bill, yellowish white iris, and white auricular plumes from eye across ear-coverts; dark sooty grey upperparts, wings and tail, brownish grey underparts; legs and feet grey, with black claws. Sexes similar, female with slightly smaller and less recurved bill, possibly shorter crest. Distinguished from all other auklets by all-dark body plumage. In winter, bill smaller and dull yellow, lacking accessory plates; crest and auricular plumes somewhat reduced. Juvenile similar to winter adult, but lacks crest and auricular plumes; bill smaller, dull brownish yellow.
Habitat. Offshore and along sea coasts. Breeds on remote islands and coasts, utilizing scree slopes, boulder fields, lava flows and sea cliffs, sometimes with partial vegetative cover (mosses, grasses, herbs), usually in association with other auklet species; density highest on unvegetated scree. Forages in deep water, often far offshore, concentrating in areas where physical dynamics of water system cause dense aggregations of zooplankton to occur: regions of converging currents, upwellings, tidal pumps, stratified waters. Mostly pelagic in winter, usually in large flocks, remaining in ice-free waters of breeding range S to Japan and Gulf of Alaska, particularly near Kodiak I.
Food and Feeding. Forages mainly offshore in deep water, sometimes in near-shore regions, almost always in large flocks throughout year. Adult diet during summer believed similar to chick diet; adults in N Sea of Okhotsk ate chiefly euphausiids (*Thysanoessa*; 88% by number). Chicks fed high diversity of invertebrates, mostly planktonic crustaceans, especially *Thysanoessa*, but also copepods, gammarids, hyperiids, mysids, infrequently small fish and squid; at St Lawrence I mainly *Thysanoessa* (56-80% by number), supplemented by varying amounts of *Calanus finmarchicus*, *C. marshallae*, *Neocalanus plumchrus*, *N. cristatus*, Caridea, Mysidacea and other crustaceans; 1-4 meals/day, average meal size 21 g (4·7-36·3 g) and daily total of c. 80 g; food carried by both parents in sublingual throat pouch, feeding rate higher in female than in male. Summer foods usually obtained at considerable distance from colony, often 50 km away, sometimes closer (5 km), at depths to 30 m. Winter foods unknown, suspected to be largely marine invertebrates.
Breeding. Spring arrival Mar-May, with colony attendance from late Apr (Aleutians), early May (Pribilofs), late May (St Matthew I) or early Jun (St Lawrence I); peak laying late May in W Aleutians, early Jun in Pribilofs, mid- to late Jun at St Matthew I, early Jul at St Lawrence I; late snow-melt can delay laying at N colonies; fledging peaks early Aug (Aleutians), mid-Aug (Pribilofs) and early Sept (St Lawrence). Monogamous, with high site and mate fidelity throughout breeding life; both sexes prefer mates with large crests (correlates with agonistic superiority). Colonial, normally in large groups, with some colonies larger than 100,000 pairs (e.g. Talan, Matykyl, Talus Is); densities determined largely by availability of suitable rock crevices and cavities for nesting, highest on unvegetated scree; usually synchronous (e.g. 80% of hatchings within 10-day period). 1 egg; incubation averages c. 34-35 days, shared equally between sexes, shift length unknown; lost first eggs rarely replaced; downy chick c. 25 g, semi-precocial, brooded more frequently by male to 10th day but female delivers more meals; chick-rearing averages 33 days (27-36). Breeding success variable, average c. 52-55% (48-57%) of eggs laid producing fledglings, with annual productivity c. 0·50-0·55 young fledged/pair. Most egg and chick losses due to predation by foxes (*Alopex lagopus*, *Vulpes vulpes*), voles (*Microtus*) and rats (*Rattus*); fledglings vulnerable to avian predators at time of departure. Information on survival limited: adult annual survival estimated at 86% (1-year data) or lifespan of c. 8 years; pre-breeding survival unknown. Age of first breeding not known, probably 3-4 years.
Movements. Very little known of migratory movements. Autumn exodus occurs in Sept, but winter range poorly documented. Believed to be pelagic, remaining largely within ice-free waters of breeding range except for movements SW to Japan and SE into Gulf of Alaska (Kodiak I region). Birds concentrated into flocks, often in large numbers, up to 15,000 birds, at predictably food-rich offshore locations. Reoccupation of colony areas begins in Mar through May, with first landings from late Apr (Aleutians) to early Jun (St Lawrence I).
Status and Conservation. Not globally threatened. Breeding population size unknown, but North American population estimated at c. 3,000,000 individuals (roughly 2,100,000 pairs) and Russian population around 2,900,000 birds (c. 2,000,000 pairs): total of almost 6,000,000 breeding birds, or 4,100,000 pairs. Largest numbers are at Talan I (1,000,000 birds) and Matykyl I (300,000-400,000 birds) in W (N Sea of Okhotsk), and Kiska I, C Aleutians (Sirius Point: 332,000 birds), and St Lawrence I (Kongkok Bay: 455,000 birds) in E. Estimates very approximate, however, and considerably more census work required; values for Alaska likely low (suspected to be c. 6,000,000 birds) and for Russia high (suspected to be c. 3,000,000 birds). Population sizes and trends little known throughout breeding range. Local changes, however, indicate overall population either stable at reduced level, or in decline. Certain large Alaskan colonies have recently become extinct (e.g. Kagamil and Uliaga in Aleutians) or substantially reduced (e.g. Kiska in Shumigan Is) owing to introduced foxes and rats; present total Aleutian population probably only small fraction of past numbers. Suspected increases at St Lawrence I during 1964-1987 and St George I in 1976-1982 are encouraging, but both may merely reflect differing census techniques or change in adult colony attendance, or both. In NE & SE Russia, human predation and disturbance combined with introduction of foxes, rats, mink (*Mustela*) and cats were serious threats during first half of 20th century, with unknown effects on populations, though major colony declines and extirpations probably occurred (e.g. Kurils and elsewhere). Current threats in both regions come from continued impacts of human predation and habitat disturbance, introduced mammalian predators, commercial fishing, and oil pollution. Species is particularly vulnerable to oil pollution through habit of forming large concentrations at sea all year round. Further studies urgently required on effects of marine pollution and commercial fisheries; also continued examination of effects of introduced predators and prevention of future introductions, particularly rats. Considerable effort required to enhance census methods to permit better assessments of colony-specific changes and to allow meaningful monitoring system to be established.

17. **Whiskered Auklet**

Aethia pygmaea

French: Starique pygmée **German**: Bartalk **Spanish**: Mérgulo Bigotudo
Other common names: Pygmy Auklet

Taxonomy. *Alca pygmæa* Gmelin, 1789, Bering Sea.
Race *camtschatica* proposed for birds from Kuril Is based on differences in body size, but recent studies confirm existence of simple clinal variation only, with size increasing from E to W. Monotypic.
Distribution. NE Sea of Okhotsk (Yamskie Is, Penzhin Gulf, Jona I) and Commander Is S to at least C Kuril Is, and throughout Aleutians E to Krenitzen Is and Four Mountains Is. Winters mostly near breeding locations, but S as far as Japan (Honshu, Shikoku), and casual in N Bering Sea (e.g. St Lawrence I).

Descriptive notes. 17-18 cm; c. 116 g (99-136 g). Unique head pattern, with long recurved crest on forehead drooping forward over small white-tipped scarlet bill; two white facial plumes running back from near base of upper mandible, and third white plume extending from back of eye across ear-coverts; blackish upperparts and breast, white belly; legs and feet greyish, with blackish webs and dark grey-black claws. Female usually smaller in most measurements (weight, culmen, wing, tarsus). Differs from all other species by head pattern, and small size (only *A. pusilla* is smaller). In winter, crest shorter and facial plumes less distinct. Juvenile resembles winter adult, but lacks crest and has bill dull yellow with blackish tip; separable from other auklets by three whitish streaks on side of face.
Habitat. Offshore and along sea coasts. Breeds on bare to partially covered talus slopes and beach boulder fields, and lava flows on high slopes of rocky islands and sea cliffs, usually with other *Aethia* but in lower numbers, habitats ranging from immediately above high water mark to tops of maritime rocky slopes and cliffs; density highest in unvegetated talus. Forages in near-shore waters close to breeding site, in areas of upwelling and converging currents. In winter mostly near-shore off rocky sea coasts and islands within breeding range, sometimes pelagic.
Food and Feeding. Diet throughout year marine zooplankton. Detailed information lacking, but summer foods at Buldir I (Aleutians) showed high diversity of crustaceans, with copepod *Neocalanus plumchrus* dominant (76% frequency), followed by euphausiids and chaetognaths (probably *Thysanoessa inermis* and *Sagitta elegans*, respectively). Food delivered by both parents, usually at night, carried in sublingual throat pouch and regurgitated to chick; meal size unknown, but 2 meals/

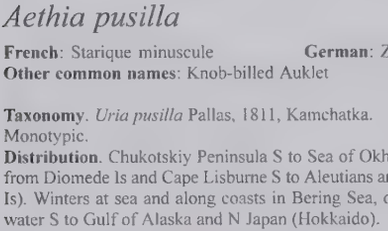
day is suspected maximum. Winter food poorly known, but limited information indicates euphausiids and gammarid amphipods are principal prey outside breeding season, with euphausiids (mostly *Thysanoessa inermis*) comprising over 90% (wet weight) during Sept-Apr (E Aleutians). Forages near-shore, in summer usually within 10 km of colony, sometimes farther off, most often in flocks concentrated at food-rich locations. Diving depths unknown, but normally found in waters not exceeding 100 m.

Breeding. Breeding phenology poorly known. Spring arrival Apr to early May; laying probably late May and early Jun, sometimes advanced; hatching appears synchronous, usually late Jun to early Jul, with fledging mid-Jul to mid-Aug, sometimes earlier. Probably monogamous. Colonial in high numbers, often with other crevice-nesting species (usually *A. cristatella*, *A. pusilla*), but always in lower numbers than congeners in mixed colonies; density determined largely by availability of suitable habitat, highest in unvegetated talus. Nests in rock crevices, also in mixed rock-soil substrates. 1 egg; incubation period uncertain, probably c. 35-36 days, by both sexes, with early egg losses probably replaced; downy chick 12-14 g, semi-precocial; chick-rearing period poorly known, probably longer than for other *Aethia*, at least 39-42 days, with fledged chick departing after dark by flying to sea, usually fully feathered and alone. Annual breeding success 73%, with normally high hatching (82%) and fledging (85%) success. Some egg and chick losses due to aggressive encounters with other *Aethia*, also predation by introduced rats (*Rattus*) and foxes (*Alopex lagopus*, *Vulpes vulpes*). Adults vulnerable to Peregrine Falcon (*Falco peregrinus*), Bald Eagle (*Haliaeetus leucocephalus*) and Glaucous-winged Gulls (*Larus glaucescens*), but mortality low owing to nocturnal behaviour. Adult survival estimated at 80%, pre-breeding survival rate not known. Age of first breeding unknown, probably 3-4 years.

Movements. Distribution and movements outside breeding season poorly known. Returns to colonies Apr to early May, with reproduction complete by mid-Aug, and most birds gone by early Sept. Most birds probably remain near-shore close to breeding areas (e.g. Aleutians), others possibly undergo local movements to adjacent seas (e.g. some Kuril birds to S Japan). Often concentrated in large flocks in winter, presumably at food-rich locations, particularly in E Aleutians.

Status and Conservation. Not globally threatened. Total population small, second rarest alcid in Alaska. Numbers poorly known, but coarse estimates indicate minimum of 100,000 birds, with 75,000 in North America (mostly E Aleutians) and 25,000 in Russia; alternatively something under 100,000 pairs. Largest concentrations at Buldir I (30,000 pairs), Krenitzen Is, Four Mountains Is, and several sites from Atka Pass to E Sitkin Sound; few count data in W, but probably significant numbers at Commander Is (Yama I, 2000 birds), Kurils (Chirinkotan, Matua, Ushishir), and N Sea of Okhotsk (Yamskie Is, c. 1000 pairs). Although estimates coarse, particularly W of Buldir I, sufficient to indicate high vulnerability to human activity. Information on population trends unavailable; incidence of accidental introductions of rats and persistence of introduced foxes on some breeding sites give cause for concern. Most serious current threats from introduced mammalian predators on colonies, oil pollution at sea, and fatal attraction to ship lights at night, particularly near colonies. Protection of breeding habitat critical, as is development of monitoring system capable of determining breeding performance and status at major breeding locations (a formidable task owing to species' nocturnal colony behaviour and breeding habitat characteristics).

Bibliography. Armstrong (1983), Bailey (1993a, 1993b), Bailey & Kaiser (1993), Bent (1919), Brazil (1991), Byrd (1994), Byrd & Day (1986), Byrd & Gibson (1980), Byrd & Williams (1993b), Byrd *et al.* (1983), Day & Byrd (1989), Dementiev & Gladkov (1951b), Feinstein (1959), Flint & Golovkin (1990), Flint *et al.* (1984), Gizenko (1955), Golovkin (1984), Gould *et al.* (1982), Haney, Hood *et al.* (1991), Hipfner & Byrd (1993), Hunt, Harrison & Piatt (1993), Johnsgard (1987), Knudtson & Byrd (1982), Knystautas (1993), Kondratiev (1991), Kozlova (1957), Lensink (1984), Litvinenko & Shibaev (1991), Manuwal (1984), Murie (1959), Sowls *et al.* (1978), Springer *et al.* (1993), Stejneger (1885), Troy (1989), Troy & Bradstreet (1991).



18. **Least Auklet**

Aethia pusilla

French: Starique minuscule **German**: Zwergalk **Spanish**: Mérgulo Mínimo
Other common names: Knob-billed Auklet

Taxonomy. *Uria pusilla* Pallas, 1811, Kamchatka.
Monotypic.

Distribution. Chukotskiy Peninsula S to Sea of Okhotsk (Yamskie Is) and C Kuril Is, and W Alaska from Diomede Is and Cape Lisburne S to Aleutians and E to NW Gulf of Alaska (Sumigan and Semidi Is). Winters at sea and along coasts in Bering Sea, often near breeding areas, from N limits of open water S to Gulf of Alaska and N Japan (Hokkaido).

Descriptive notes. 12-14 cm; c. 85 g; wingspan 33-36 cm. Smallest alcid; short, dull red bill with narrow pale tip and blackish base, small horny knob from base of upper mandible; head dark, with white bristly feathers on forehead and lores, and white streak behind eye; white throat and dark breast band diagnostic; dark grey upperparts with white scapular streaks; underparts variably white to blackish grey, with mottled grey commonest. Female has slightly shallower bill. Distinguished from other species by tiny size, and head pattern. In winter, underparts entirely white, bill blackish without knob, and most facial plumes absent. Juvenile resembles winter adult, but lacks white auricular streak.

Habitat. Marine offshore and along coasts. Breeds on remote islands and sea coasts in talus slopes, beach boulder rubble, sea cliffs and lava fields where crevices suitable for breeding are abundant, usually in bare talus (where breeding density highest), occasionally in partially vegetated talus slopes or cliffs, almost always in association with other auklet species. Forages offshore in open ocean, often where upwelling, tidal pumps, etc. concentrate zooplankton (particularly copepods) near surface. Winter range and movements poorly known, but mostly pelagic and along sea coasts within breeding range.

Food and Feeding. Forages on planktonic crustaceans near-shore to offshore throughout year, almost always in large flocks and at open ocean locations with certain physical characteristics, especially stratified waters with strong thermoclines and upwellings. During breeding season, major foods of adults and chicks are calanoid copepods, principally *Neocalanus* (especially *N. plumchrus*), supplemented by numerous other small crustaceans: euphausiids, gammarids, hyperiids and mysids (St Lawrence I, Pribilofs, King I studies). Parents carry food in sublingual throat pouches and deliver 1-4 meals each daily (mean 2·6 meals/parent/day); average meal size from 5·4 g (0·9-12·3 g) at St George I to 8·2 g (6-10 g) at St Paul I, giving daily chick food intake of 28-43 g. Summer foods obtained at varying distances from colony, up to c. 50 km. Winter food not examined, probably variety of planktonic invertebrates. Dives to depths usually above c. 15 m, infrequently 25 m.

Breeding. Spring arrival at colonies variable, earliest towards extreme S, latest at N limit: late Apr to early May in Aleutians, early to mid-May at Pribilofs, late May at St Matthew I, and early to mid-Jun at St Lawrence I and Bering Strait site. Peak laying also earliest in S: usually late May in W Aleutians, early Jun in Pribilofs, mid- to late Jun at St Matthew, eary Jul at St Lawrence; laying at N colonies can be delayed by late snow-melt; fledging peaks early Aug (Aleutians), mid-Aug (Pribilofs), and late Aug to early Sept (St Lawrence). Monogamous, with shared mate choice and relatively low mate fidelity between years; both sexes prefer partners with elaborate facial ornaments (no relationship between degree of ornamentation and bird quality documented). Highly colonial, in large to enormous colonies, many exceeding 100,000 birds and some more than 1,000,000; numbers and density determined largely by availability of suitable habitat and crevices; usually highly synchronous (80% of hatchings within 10-day period). 1 egg; incubation averages c. 30-31 days, by both sexes in shifts of 12-36 hours (mean 23·6); egg losses rarely, if ever, replaced; downy chick brown above, greyish brown below, c. 11 g, semi-precocial, brooded continuously by parents during 1st week, infrequently thereafter; chick-rearing averages 29 days (25-33), chick independent at departure. Breeding success variable within and between colonies, with overall averages of eggs laid producing fledglings 56·5% at Buldir (1976, 1988-1991), 69·7% at St George (1981/82) and 37·6-49·6% at St Lawrence (1987); variation partly due to differences in human disturbance. Overall average annual productivity probably c. 0·5-0·6 young fledged/pair. Most egg and chick losses due to foxes (*Alopex lagopus*, *Vulpes vulpes*) and small voles (*Microtus*) and rats (*Rattus*); chicks especially vulnerable to gulls and foxes at time of fledging. Mean adult annual survival 75-77%, giving life expectancy of 7-8 years; pre-breeding survival rates not known. Sexual maturity at 3 years, but proportion of 3-year-olds that breed is unknown.

Movements. Migratory movements and winter range poorly known. Normally departs from colonies Aug to early Sept (exodus latest in N), wintering largely in seas within breeding range where waters remain ice-free, with some S movement into N Pacific, infrequently S to N British Columbia and N Japan (Hokkaido). Arrives back on land at colonies from late Apr to mid-Jun, non-breeders appearing 3-4 weeks later than breeders.

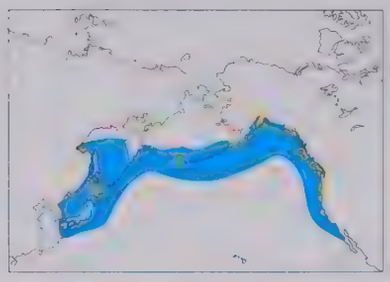
Status and Conservation. Not globally threatened. Size of breeding population unknown, but believed to be most abundant seabird in Bering Sea and most numerous auklet in Pacific. Estimates for North American population c. 9,000,000 birds or c. 6,300,000 pairs, and of and Russian population minimum c. 8,000,000 birds or c. 5,600,000 pairs, giving total of 17,000,000 birds or c. 12,000,000 pairs. Concentrated at small number of huge colonies: Matykyl I (Yamskie Is, N Sea of Okhotsk), at least 6,000,000 individuals and possibly as many as 10,000,000; St Lawrence I, 1,300,000 birds: Kiska I, 1,200,000 birds; Diomede Is, c. 1,000,000 birds; and St Matthew and Hall Is, c. 300,000 birds each. Absence of adequate census methods limits estimates to educated best guesses, offering little opportunity to assess population trends. In Alaska, local changes at some individual colonies are known: large increases at Skruis Point (Kiska I) and decreases elsewhere; marked declines at St George I (Ulakaia Hill) and St Paul I due to habitat destruction and alteration, and possible increases at St Lawrence I (Kongkok Bay, 1964-1987). Hunting, habitat destruction and disturbance, introduced predators, and effects of marine pollution (oil and fish-waste discharges) suspected prime causes of declines. Introduced rats and foxes serious threats, especially in Aleutians and Pribilofs; increases on St Lawrence may be related to reduced predation pressures from foxes and humans owing to declines in fox abundance and in importance of auklets in subsistence economies of local residents, and also to oceanographic changes in Bering Sea. Populations in NE Russia similarly affected; most serious current threats in NW Pacific include continued mortality from human predation and colony disturbance, alien predators, oil pollution and industrial developments (e.g. E Sakhalin, Sea of Okhotsk) and commercial fisheries. Overall, present conservation needs for this abundant, but vulnerable, species are: development of statistically meaningful census methods to monitor size and status of representative breeding populations throughout range; further examination of effects of introduced predators and human exploitation on populations, and enactment of necessary control measures; careful assessment of possible impacts of oil pollution and commercial fishery developments; and enforcement of existing laws and regulations to reduce disturbance and destruction of seabird colonies and habitat.

Bibliography. Anon. (1991b, 1993e), Armstrong (1983), Bailey (1993a, 1993b), Bailey & Kaiser (1993), Bédard (1969a, 1969b), Bédard & Sealy (1984), Bent (1919), Bradstreet (1985), Brazil (1991), Byrd *et al.* (1983), Flint *et al.* (1984), Godfrey (1986), Haney (1991), Harrison (1978), Hatch & Hatch (1983), Hipfner & Byrd (1993), Hunt & Harrison (1990), Hunt, Burgeson & Sanger (1981), Hunt, Eppley *et al.* (1981), Hunt, Harrison & Cooney (1990), Hunt, Harrison & Piatt (1993), Johnsgard (1987), Jones (1989, 1990, 1992a, 1992b, 1993a), Jones & Montgomerie (1991, 1992), Knudtson & Byrd (1982), Knystautas (1993), Kondratiev (1991), Konratiev *et al.* (1993), Lensink (1984), Litvinenko (1993), Litvinenko & Shibaev (1991), Manuwal (1984), Piatt, Roberts & Hatch (1990), Piatt, Roberts, Lidster *et al.* (1990), Roby (1991), Roby & Brink (1986a, 1986b), Roby & Ricklefs (1986), Sealy (1968, 1975d, 1982), Searing (1977), Sowls *et al.* (1978), Springer & Roseneau (1985), Springer *et al.* (1993).

Genus *CERORHINCA* Bonaparte, 1828

19. **Rhinoceros Auklet**

Cerorhinca monocerata



French: Macareux rhinocéros **German**: Nashornalk **Spanish**: Alca Unicórnea
Other common names: Horn-billed/Unicorn Auk

Taxonomy. *Alca monocerata* Pallas, 1811, Cape St Elias, Alaska.
Monotypic.

Distribution. Akademii Gulf, S Sakhalin and S Kuril Is to Japan (Teuri I) and extreme NE Korea; C Aleutians; S & SE Alaska (W to Barren I, Middleton I, St Lazaria I, Forrester I) S to British Columbia (Triangle I), W Washington (Destruction I) and N California (Castle I, Farallon Is). Winters mostly offshore and along coasts, in Asia near breeding areas, and in North America mainly from S British Columbia (casually from SE Alaska) S to Baja California (Santa Margarita I).

Descriptive notes. 35-38 cm; c. 533 g. Yellowish orange bill, with short, vertical whitish knob or "horn" at base of upper mandible; darkish brown head with yellow iris, and with two long white facial plumes extending backwards, one from above eye to nape and the other from gape to upper throat; brownish upperparts, with pale buff edges giving faint scaled appearance; brownish upper breast, whitish belly, flanks with broken pale brown barring; legs and feet greyish yellow, with black webs and claws. In winter, knob of upper mandible absent, and white facial plumes less distinct; resembles immature *Fratercula cirrhata*, but has smaller, more pointed bill and pointed wings. Juvenile similar to winter adult, but bill smaller and no facial streaks.

Habitat. Marine offshore and along sea coasts and islands. Breeds on maritime and inland grassy slopes, sometimes on flattish ground, on small forested and unforested predator-free islands, rarely on steep island or mainland cliffs; also occurs in large aggregations at sea, and often forms dense roosting

flocks at night in sheltered bays. In winter, normally pelagic in waters offshore from breeding areas, sometimes in near-shore coastal waters where coastal oceanographic conditions (upwellings, converging currents, tidal pumps) concentrate food. Winter ecology poorly known, but mostly pelagic within breeding range.

Food and Feeding. Mostly fish throughout year, supplemented in winter by small amounts of invertebrates (squid, euphausiids and other crustaceans); generally opportunistic, with diverse and seasonably variable diet, including relatively high consumption of crustaceans. Chick diet almost exclusively fish, but invertebrates may appear for late-hatched young; c. 2 meals/day, delivered by both parents at night, averaging c. 30 g of fish/meal or c. 60 g daily, usually of species high in fat, e.g. sandeels (*Ammodytes hexapterus*), capelin (*Mallotus villosus*). Food studies limited, but principal prey fed to young known to vary geographically: e.g. sandeels, bluethroat argentines (*Nansenia candeda*), Pacific saury (*Cololabris saira*) and rockfish (*Sebastes*) predominated in British Columbia (Triangle I), whereas main foods in nearby Washington (Destruction I) were sandeels, Pacific herring (*Clupea harengus*) and northern anchovy (*Engraulis mordax*) with lesser amounts of surf smelt (*Hypomesus pretiosus*) and night smelt (*Spirinchus starksi*); capelin important at N colonies. Adult summer diet appears similar to foods delivered to chick; winter diet little known, but available information indicates small fish (anchovies, rockfish), crustaceans and squid. Generally forages inshore, often in mixed-species flocks, at locations near colony or far offshore. Pelagic schooling fish obtained by pursuit-diving, mostly at depths above 30-40 m.

Breeding. Arrival at colony normally late Mar and early Apr, slightly later in N; laying from end Apr to mid-Jun, with fledging mostly late Jul to early Sept. Monogamous, with site and mate fidelity probably high, but degree of mate retention unconfirmed. Highly colonial, in small to very large concentrations (some exceeding 100,000 birds), usually with other alcids; usually at high densities on optimal grassy-turf habitat, averaging 0·2-1·2 pairs/m², sometimes higher; laying often highly synchronous within colony (80% of eggs laid within 14-16 days), but timing variable between populations. Lays in nest chamber at end of burrow, usually 2-3 m long (up to c. 6 m), excavated by both sexes, primarily in exposed grassy maritime slopes or flat ground on forest floor. 1 egg; incubation averages 35 days, by both sexes for stints of 24 hours; early egg losses may be replaced after 9-14 days; downy chick mostly dark greyish brown, slightly paler below, c. 54-57 g, semi-precocial; chick-rearing averages 52 days (annual variations 48-60 days, likely related to food supply), with care and feeding by both parents until fledging, when chick leaves burrow at night and flies to sea unaccompanied, usually fully feathered. Breeding success variable within and between colonies, overall average 56% eggs laid producing fledglings; hatching 81% (65-94%), fledging 69% (27-97%), with lower variation in hatching success than chick survival probably related to inter-year differences in food supply during chick rearing. Egg losses due to breakage, neglect, and predation by gulls and, locally, introduced mammals; chick losses due mainly to food shortage (starvation, or increased exposure to predators). Adult annual survival and recruitment rates not known. Age of first breeding uncertain, probably 5 years.

Movements. Winters mostly offshore, sometimes near-shore and coastal, usually within breeding range. S populations somewhat sedentary, often remaining in coastal and offshore waters adjacent to colony; N birds (Alaska) mostly migratory, moving S to at least S British Columbia. N and inshore movements from wintering areas begin as early as Feb-Mar, most birds reaching colonies in late Mar and Apr.

Status and Conservation. Not globally threatened. Total breeding population estimated at 1,250,000 birds, with c. 347,000 (300,000-400,000) in Asia and c. 903,000 (800,000-1,000,000) in North America, mostly in boreal waters, with centre of abundance in British Columbia. Largest single colonies in Japan (Teuri I, c. 350,000 birds), SE Alaska (Forrester I, 108,000 birds) and British Columbia (Pine I, 90,000 birds). Regional totals of c. 334,000 birds in Sea of Japan (Hokkaido), 10,000 in Kurils, 3000 in Sea of Okhotsk, 119,000 in Alaska (110,000 in SE), 903,000 in British Columbia, 61,000 in Washington, 1000 in Oregon, and under 2000 in California. Historically, population probably much larger than at present, though data insufficient to define precise trends in most regions. In general, populations from Kurils NE to Alaska drastically reduced during 19th and first half of 20th centuries through introduction onto nesting colonies by Japanese and Russian fur-farmers of foxes (*Alopex lagopus*, *Vulpes vulpes*), sable (*Martes zibellina*), ermine (*Mustela erminea*) and mink (*Mustela vison*, *M. lutreola*), and associated rats (*Rattus norvegicus*), voles (*Microtus*), feral cats and dogs, and use of the birds for animal feed. Many colonies extinct, and pressures from alien predators continue today. Numbers in Russia declined from c. 14,000 birds in 1938 to 1500 in 1949, from which level they have not recovered. In Alaska, many former island populations were probably extirpated by introduced foxes throughout SW, SC & SE regions including Aleutians, where now restricted to Buldir I (fewer than 1000), the only fox-free island. Populations farther S in North America were also seriously affected, mostly by human disturbance (egging and hunting, destruction of nesting habitat, lighthouse construction and operation) and by introduced mammals, both predators and domestic livestock. Many extant populations remain threatened by continued presence of introduced ground predators (especially Kurils, Russia, Alaska), but some have shown or are showing significant increases: California, Farallon Is recolonized in early 1970's after extirpation in 1860's, and substantial increase since rabbits removed in 1974; Washington, 700+% increase on Protection I after removal of sheep in 1968; British Columbia, on Cleland I; and Japan, on Teuri I during 1950-1970. Currently, numbers believed relatively stable in Japan, decreasing in Russia, stable or slightly increasing elsewhere. Major threats remain continued predation by introduced mammalian predators at nesting colonies, oil spills in vicinity of major colonies during breeding season and where birds concentrate at sea during winter, commercial fisheries (direct mortality in gill-nets, food shortages during chick-rearing from overfishing), and disturbance at colonies during summer (tourism, researchers). Immediate conservation needs include: increased effort to control and eradicate introduced predators on extant and former breeding colonies; establishment of widespread monitoring system to obtain accurate information on population size and reproductive performance; refinement of existing census techniques; initiation of studies to examine pelagic ecology and winter requirements; further assessment of direct and indirect impacts of commericial fisheries; and development and implementation of more effective system of protection of major breeding colonies.

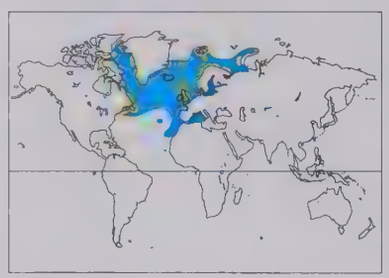
Genus *FRATERCULA* Brisson, 1760



20. **Atlantic Puffin**

Fratercula arctica

French: Macareux moine **German**: Papageitaucher **Spanish**: Frailecillo Atlántico
Other common names: (Common) Puffin

Taxonomy. *Alca arctica* Linnaeus, 1758, northern Norway.
Recorded differences separating *grabae* from nominate *arctica* may reflect clinal variation only. Three races recognized.

Subspecies and Distribution.
F. a. naumanni Norton, 1901 - NE Canada (high E Arctic) and NW & E Greenland to Jan Mayen, Spitsbergen and N Novaya Zemlya.
F. a. arctica (Linnaeus, 1758) - SE Baffin I and Hudson Bay S to Maine, and E through SW & S Greenland and Iceland to Bear I, C & N Norway, Kola Peninsula and S Novaya Zemlya.
F. a. grabae (C. L. Brehm, 1831) - Faeroes, S Norway and SW Sweden S through British Is to Channel Is and NW France.
Winters at sea, mostly in boreal waters S to New Jersey, Azores, Canary Is, and W Mediterranean, rarely to Virginia and NW Africa.

Descriptive notes. 26-36 cm; 460 g; wingspan 47-63 cm. Large, triangular red bill, laterally compressed, with distinct transverse ridges across upper mandible, bluish grey at base with pale yellow cere, and orange-yellow rictal rosette at gape, yellowish mouth and tongue; mostly white to greyish white face, with narrow black band from forehead to nape, greyish chin, and pronounced dark post-ocular stripe; small fleshy-grey protuberances above and below orange-red eye-ring, and soft brown iris; mostly black upperparts; black from neck across throat, with snow white breast, flanks and belly; legs and feet orange to yellowish orange or reddish, with sharply recurved black claws. Differs from larger *F. corniculata* by bill and facial ornaments. In winter, eye ornaments, basal-plate sheath of mandible and cere absent, making bill smaller; face darker grey, bare part colours less distinct. Juvenile resembles adult, but generally smaller (overlap between small adult females and large juveniles); bill and legs duller; fewer than 2 transverse ridges on upper mandible. Races differ only in size, but with much individual variation and overlap.

Habitat. Exclusively marine, occurring along rocky coasts and offshore islands. Breeds on grassy-turfed maritime slopes or adjacent flattish ground, also on sea cliffs, and boulder fields and scree slopes. Almost 60% breed in boreal water zone, 40% in low Arctic waters and less than 1% in high Arctic marine zone. In winter, wide-ranging in offshore and pelagic habitats, normally within open-water regions of breeding range to edge and slope of continental shelf, only infrequently into open ocean, and rarely beyond S limit of boreal waters into cool subtropical waters. Winter distributions poorly known, but principal determinants probably sea surface water temperatures and distribution patterns of key pelagic fish species.

Food and Feeding. Mostly fish throughout year, supplemented mainly late summer to spring by small crustaceans (euphausiids, copepods), polychaetes (nereids) and squid; daily food intake estimated at c. 15-20% of adult body weight. Typically neritic feeder during breeding, obtaining food inshore out to edge of continental shelf, with foraging patterns highly variable between areas and water systems during chick-rearing, from feeding close (3-5 km) to colony to travelling considerable distances (50-100 km) away; birds often gather offshore at edges of banks where water-mass boundaries or fronts and flow gradients concentrate fish prey. Food brought to chicks almost exclusively fish, except late in rearing period when invertebrates may appear, with principal prey species varying between area and water type, but all with relatively high calorific values, primarily small pelagic fish: capelin (*Mallotus villosus*) in low Arctic waters (Labrador, Newfoundland); sandeels (*Ammodytes*, *Hyperoplus*), Atlantic herring (*Clupea harengus*), Atlantic mackerel (*Scomber scombrus*) and gadids in N boreal waters (N Norway); sandeels, sprat (*Sprattus sprattus*) and gadids in S boreal regions (Britain). In general, all colonies of race *grabae* are in areas with sprat, whereas most colonies of race *arctica* are where there is a capelin fishery, and movements of birds from these low Arctic sites seem associated with capelin movements. Chick fed by both parents, c. 3-9 meals/day, averaging total of 43-62 g daily. Winter diet poorly known. Feeds by underwater pursuit-diving, usually after schools of fish (rather than single individuals), to depths normally above 20 m, with average dive times under 30 seconds.

Breeding. Arrival and start of laying variable between regions, usually earlier and with more extended pre-laying and laying periods at extreme S locations, later and with time periods reduced in low Arctic zone; average arrival in boreal waters mid- to late Feb (E Scotland) and late Mar to early Apr (Wales, Scotian Shelf, Gulf of Maine), in low Arctic normally mid-Apr (Murmansk, N Norway, Newfoundland, N Gulf of St Lawrence), sometimes 1st half Jun (Labrador), in high Arctic waters unknown (probably later than low Arctic); most laying early to late May or early Jun, earlier in E Scotland and later in Labrador and high Arctic; fledging normally through Jul and early Aug, later in low and high Arctic. Monogamous, with high mate and site fidelity. Highly colonial, in small to large aggregations; densities highest on seaward-facing slopes, averaging 2·0 pairs/m² (1·7-2·8); usually highly synchronous within a colony, often most precisely so among birds on slope habitat. Nests mostly in burrows excavated (1-2 m long) in turf-covered maritime steep slopes and level tops, also in rock crevices and interstices on cliffs and cavities in boulder fields and scree slopes; males spend more time defending and maintaining burrow than females; usually lays on scrape, often lined with dry grass and feathers, in nest chamber at end of tunnel. 1 egg; incubation averages 42 days (36-45 days), by both sexes (females slightly longer) for variable periods averaging c. 32 hours (23-70); early egg losses may be replaced after c. 13-23 days, but replacement rate low (c. 9%); downy chick silvery grey above, white on belly, with black legs and bill, c. 48 g, semi-precocial; chick-rearing variable, averages 38-59 days (39-83), with care and feeding by both parents, chick normally fledging at night soon after dark and flying out to sea unaccompanied, usually fully feathered except late-hatched young, which often depart with considerable down. Breeding success highly variable, averaging from 28% to 93% at different colonies and years through N Atlantic (excluding years of total failure owing to severe food shortages); in average conditions c. 53%, with mean survival of eggs (72% laid hatch) and chicks (73% hatched fledge) very similar; higher in regions of unusual population growth (e.g. Isle of May, E Scotland) and lower on low-quality habitat (e.g. flattish ground in presence of gulls, Great I, Newfoundland) or where fish-

stock collapses have occurred (Norway, Atlantic Canada). Factors causing egg and chick losses variable, from parental neglect or mishandling during incubation and brooding to gull predation and food shortages during chick-rearing; human predation and disturbance significant in many regions. Adult survival c. 95%; survival of fledglings to breeding age variable, 13-39%. First breeding normally at 5 years, sometimes 3 or 4 when population expanding.

Movements. Winters largely offshore, widely dispersed at relatively low densities, sometimes off continental shelf and slope into pelagic zone. Post-breeding dispersal complex, with four basic patterns: Greenland and Newfoundland birds remain in W Atlantic, well offshore and dispersed widely; Irish Sea birds and some from N Britain move S to Bay of Biscay, and probably Mediterranean; birds from E Britain, SW Norway and some from N Britain winter mostly in North Sea; those from Murmansk, N Norway, Iceland and European high Arctic and some 1st-winter birds from N Britain move W or SW; younger cohorts from all these regions move longest distances, as far as Greenland and Newfoundland. Extent and magnitude of S movement during winter poorly known, but birds from S colonies appear to migrate farthest S, recorded regularly to W Mediterranean and NW Africa (Morocco) in E Atlantic and to New Jersey in W Atlantic. Return to breeding areas prolonged, with colonies usually occupied by breeders between mid-Mar and mid-May, indicating that spring movements begin during Feb and early Mar. Considerably more work required to identify main wintering areas and clarify patterns of movement.

Status and Conservation. Not globally threatened. Total breeding population estimated at c. 6,000,000 pairs (3,800,000-8,200,000), of which c. 60% in boreal zone (S Iceland to France and Norway), 40% in low Arctic waters (most of E Canada and W Greenland, N Iceland, Bear I, Kola Peninsula, S Novaya Zemlya), and less than 1% in high Arctic marine zone (N Canada, NW & E Greenland, Jan Mayen, Spitsbergen, N Novaya Zemlya). Main concentration in Iceland, with c. 3,000,000 pairs (c. 50%); Norway holds 1,200,000 (20%), Britain 675,000 (11%), Faeroes 500,000 (8%), E Canada 365,000 (6%), Ireland 45,000 (under 1%), smaller numbers elsewhere. Big concentrations during breeding season make species highly vulnerable to direct and indirect effects of disturbance from human activities. Total population significantly reduced through 18th, 19th and first half of 20th centuries, mainly through egging, hunting, uncontrolled killing of birds at colonies for food, and introduced alien predators (rats, feral cats and dogs) and grazing animals (goats, sheep, rabbits); many populations extirpated or severely reduced by expanding human populations, particularly in boreal regions and S low Arctic waters, including S parts of continental W Europe, British Is, E Canada and New England. Slow recovery occurred in some regions from 1920's to 1940's, when marine pollution began to limit and reverse trend of increasing numbers in most regions. More recently, major international fisheries developments in Barents Sea-Norwegian Sea, Irminger Sea and NW Atlantic (Grand Banks of Newfoundland) since early 1960's have resulted in overfishing causing collapses of key forage-fish species, with ensuing reproductive failure and declines of many populations of present species, e.g. Røst (Norway) 64% decline 1979-1988, and Great I (Newfoundland) c. 30% decline 1972-1989; also unknown impacts on winter survival and longevity. Food shortages combined with entanglement and drowning in fishing gear, chronic oil fouling throughout year, disturbance on nesting grounds (uncontrolled "harvesting", livestock grazing, tourism), and winter hunting pose serious threats. Populations decreasing in France, Channel Is, Norway, Kola Peninsula and E Canada, and parts of British Is and Faeroes; status in Iceland uncertain, mainly due to difficulty of monitoring the large and widespread population, though local declines highly probable. Major conservation actions required include: control of human disturbance at breeding colonies; control and removal of alien animals from colonies; major examination of impact of food shortages on populations, particularly those suspected or known to involve commercial fisheries; establishment of enhanced system to monitor and predict impacts of offshore oil developments on major populations, particularly those on critical international bird wintering areas, e.g. Hibernia and Ben Nevis fields, Grand Banks of Newfoundland; increased effort to identify ecological requirements at sea during winter; and initiation of monitoring system to determine status and population trends in Iceland and Faeroes, probably through international partnership.

21. **Horned Puffin**

Fratercula corniculata

French: Macareux cornu **German**: Hornlund **Spanish**: Frailecillo Corniculado

Taxonomy. *Mormon corniculata* J. F. Naumann, 1821, Kamchatka.
Monotypic.

Distribution. Wrangel I, Heard I and Chukotskiy Peninsula S through Kamchatka and Commander Is to Sea of Okhotsk, Sakhalin and N Kuril Is, and W Alaska (Diomede Is, Cape Lisburne) S through Bering Sea to Aleutians and E through Gulf of Alaska S to British Columbia (Queen Charlotte Is). Winters offshore and along sea coasts mostly within breeding range, but casually S to C Japan, rarely to W Hawaiian Is, also to S British Columbia and N Washington and rarely to Oregon and California.

Descriptive notes. 36-41 cm; 612 g; wingspan 56-58 cm. Large, triangular red-tipped yellow bill, laterally compressed, with orangy rictal rosette at gape, yellowish mouth and tongue; white face, with black forehead, crown, nape and chin, dark post-ocular stripe; small elongated, upright, triangular fleshy dark horn above reddish eyering; iris dark brown, almost black; black upperparts, snowy white breast and belly; legs and feet orange or reddish, with sharp, recurved black claws. Differs from *F. cirrhata* in white underparts and no nuptial facial plumes. In winter, lacks basal yellow bill plate; face greyish; orangy red of bare parts less pronounced. Juvenile similar to winter adult, but considerably smaller, with shorter and narrower, darker bill.

Habitat. Marine, occurring along sea coasts on rocky cliffs and offshore islands. Breeds mainly on rocky cliffs, boulder areas and talus slopes, less frequently in burrows on grassy-turfed maritime slopes of islands. Occurs mainly on glaciated and rocky coastlines, usually associated with relatively cold water systems. In winter, mostly offshore within open-water areas of breeding range to edge of continental shelf, only infrequently penetrating open ocean (unlike *F. cirrhata*), and rarely S beyond N half of boreal zone; winter distribution largely influenced by sea surface temperatures and associated concentrations of pelagic fish.

Food and Feeding. Predominantly inshore feeder during breeding season, usually within 1-2 km from shore, but sometimes 16 km or more out. Diet throughout year mostly fish of wide diversity of species, supplemented with significant quantities of squid, crustaceans and polychaetes. Overall, more generalized feeder than *F. cirrhata*. Chick diet almost exclusively fish, primarily sandeels (*Ammodytes hexapterus*) and capelin (*Mallotus villosus*), both unusually high in fat and calorific value, and their availability during chick-rearing a major determinant of breeding success; secondary chick foods include greenling (*Hexagrammos*), cod (*Gadus*), sandfish (*Trichondon*) and squid. Chick fed by both parents, 2-6 meals/day averaging 12 g each (8-17 g), or 24-72 g daily. Adult diet through entire breeding season mostly fish (48%), followed by squid (31%), polychaetes (12%) and crustaceans (8%); winter foods poorly known, but available information suggests similar to summer. Food obtained by underwater pursuit-diving, probably at depths above 40 m.

Breeding. Spring arrival and start of breeding variable, with major movement through Bering Sea during May and reoccupation of colonies usually mid-May to early Jun; peak laying mid-Jun to mid-Jul, with fledging mostly early Sept and continuing to end Sept. Few breeding studies, but likely monogamous, with high site and mate fidelity. Colonial, in small to large aggregations; densities largely determined by availability of suitable rock crevices and cavities, highest in less favoured vegetated talus slopes, probably reaching maximum of c. 0·2-0·5 pairs/m²; laying highly synchronous within a colony (most eggs laid within 1 week of each other). Nest typically in crevice or crack in rock substrate, usually on cliff face, also in cavities under beach boulders and talus slopes, and less frequently in burrows excavated on grassy-turfed maritime slopes of islands; lays in scrape on bare floor at end of crevice or cavity tunnel, sometimes sparsely lined with feathers or dry plant material. 1 egg; incubation averages 41 days (38-43), by both sexes; early egg losses may be replaced; downy chick pale grey-brown to dark brown above, greyish white to yellowish white on belly, with blackish bill, legs and feet, c. 59 g, semi-precocial; chick-rearing averages 40 days (38-43, but higher variation likely in relation to food supply), with care and feeding by both parents; chick normally fledging at night, flying out to sea unaccompanied, usually fully feathered. Breeding success averages 57%, with mean survival of eggs (76%) and chicks (71%) similar, though chick mortality usually more variable than egg survival. Most egg and chick losses probably due to parental neglect or food shortages, although foxes (*Alopex lagopus*, *Vulpes fulva*) significant predators at some locations, as are rats (*Rattus*). Adult survival and recruitment rates unknown, but longevity probably high. Age of first breeding uncertain, probably 4-5 years.

Movements. Winters largely offshore adjacent to breeding areas in areas of open water; widespread over continental shelf at relatively low densities. Post-breeding dispersal Sept-Oct, with N populations from Chukchi and Bering Seas mostly moving S to at least Aleutians, some remaining farther N at Commander and Pribilof Is; S populations more sedentary, including large numbers overwintering in Gulf of Alaska, but significant numbers move S to C Japan, and some regularly to S British Columbia and Washington, even to Oregon and California. In general, timing and pattern of movements poorly known, but main spring influx occurs late Apr to mid-May throughout breeding range.

Status and Conservation. Not globally threatened. Total breeding population estimated at 1,220,000 birds, with c. 292,000 (250,000-350,000) in Asia and c. 928,000 (880,000-980,000) in North America, mostly in low Arctic and boreal water zones. Centre of abundance in Alaskan Peninsula, with c. 762,000 birds, including largest known single colony of c. 250,000 breeding birds (Suklik, Semidi Is); this total combined with individuals in Aleutians (c. 92,000), Alaskan Bering Sea (58,000) and SC Alaska (c. 16,000) accounts for 76% of world population. Only other major concentration in Sea of Okhotsk, where 200,000 birds breed, with smaller numbers in Arctic Ocean (48,000 birds), Siberian Bering Sea (40,000), Kurils (c. 4000), SE Alaska (under 1000) and British Columbia (under 1000). Few quantitative data on recent population trends, but probably decimated by introduced foxes over most of range through most of 19th and 20th centuries; both Arctic and red foxes have likely had major impact on species' selection of nesting habitat, by restricting it to rock crevices and cavities inaccessible to foxes. Current threats: predation by introduced predators on nesting grounds, oil spills, direct mortality in gill-nets, and food competition with commercial fisheries. Most pressing conservation needs are: control and eradication of introduced mammalian predators at colonies; design and implementation of monitoring system at representative set of colonies throughout range to assess population trends; detailed examination of summer and winter feeding ecology, including pelagic distribution and water-habitat usage; and initiation of systematic survey and census programme for all regions.

Bibliography. 22. **Tufted Puffin**

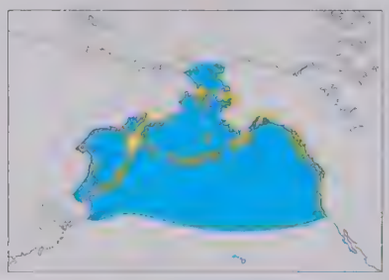
Fratercula cirrhata



French: Macareux huppé **German**: Gelbschopflund **Spanish**: Frailecillo Coletudo

Taxonomy. *Alca cirrhata* Pallas, 1769, Bering Sea.
Monotypic.

Distribution. N Japan (Hokkaido) through Kuril Is, Sakhalin and Sea of Okhotsk to N Chukotskiy Peninsula, and W Alaska (Diomede Is, Cape Thompson) S to Aleutians, E through Gulf of Alaska (Kodiak Archipelago) and S to British Columbia (Queen Charlotte Is, Triangle I) and C California (Farallon Is). Winters mostly at sea and along coasts from Kamchatka Peninsula and S Alaska S through breeding range, rarely to S Japan and S California.

Descriptive notes. 36-41 cm; 773 g. Large, parrot-like red bill, laterally compressed, basal third of upper mandible with yellowish to greenish base and yellow ridge; white face and chin, with black crown, nape and throat, and long golden to creamy-buff post-ocular tufts descending to nape; red eyering, yellow iris; black upperparts and underparts; legs and feet reddish orange, with sharp, curved black claws. Differs from *F. corniculata* and other puffin-like species in dark underparts, pale head plumes, and massive bill. In winter, head entirely dark, with no tufts; bill appears smaller and less triangular, as basal sheath absent. Juvenile has smaller yellowish bill, brown eye, and paler chin, throat and underparts.

Habitat. Marine, along rocky coasts and offshore islands. Breeds mainly in N boreal water zone, usually on maritime slopes and tops of islands, less often on cliffs or slopes of coastal cliffs and islands.

Mostly offshore during winter; one of most pelagic Pacific alcids, moving off continental shelf into oceanic zone to mid-ocean, dispersing over vast regions at very low densities; S limit usually S boreal waters, but sometimes into N cool subtropical zone.

Food and Feeding. Feeds mostly offshore on small fish, cephalopods and crustaceans throughout year. Adult diet averages c. 52% fish, 38% squid, 7% crustaceans and 3% polychaetes (by frequency of occurrence). During breeding season, often forages inshore and close to colony. Chick diet almost exclusively fish, with wide diversity over range, but Pacific sandeels (*Ammodytes hexapterus*) or capelin (*Mallotus villosus*) predominate in many E Bering Sea and Gulf of Alaska regions, often comprising 80-90%; other foods include walleye pollock (*Theragra chalcogramma*), greenling (*Hexagrammos monopoterygius*), mackerel (*Pleurogrammus monopoterygius*), cod (*Eleginus gracilis*), sculpins (*Hemilepidotus jordani*), euphausiids (*Thysanoessa*), squid and octopus, with cephalopods and pollock most important as supplementary foods. Chick fed by both parents, c. 2-4 meals/day averaging 8-20 g each, or 16-80 g daily. Little information available for E Asia; winter food poorly known throughout range. Prey obtained by pursuit-diving to considerable depths, probably above 40-50 m.

Breeding. Spring arrival latest at northernmost sites in Chukchi and Bering Seas, usually late May to early Jun, in most other regions late Apr to mid-May; laying normally peaks end May to mid-Jun, but at N sites may be 1-2 weeks later and in S is earlier, early May to early Jun, with laying period usually 1-3 weeks earlier than for *F. corniculata*; fledging mostly mid-Aug to mid-Sept, to late Sept in N. Believed monogamous, with high site and mate fidelity. Colonial, in small to immense aggregations; densites highest on steep sea-facing grassy slopes, averaging as high as 1·1 pairs/m² (Triangle I, British Columbia), normally 0·2-0·7 pairs/m² across range of habitats; laying usually highly synchronous within a colony, (often 90% eggs laid within 2-week period), variable between regions. Typically nests in shallow burrows excavated in maritime grassy-turfed slopes and flats, sometimes in crevices and cavities on cliffs, slopes and boulder beaches; lays on bare ground in rough scrape at end of burrow tunnel or crevice, usually lined with dry plant material and feathers. 1 egg; incubation averages 45-46 days (42-53 days), apparently shared equally by both sexes for periods of 12-24 hours; early egg losses may be replaced after 10-21 days; downy chick dark sooty black above, slightly paler sooty grey below, infrequently some white on underparts. 64 g, semi-precocial; chick-rearing averages 49 days, with care and feeding by both parents, chick usually fledging at night by going to sea apparently unaccompanied. Breeding success averages c. 46%, with mean survival of eggs (63%) and chicks (71%), and failure rates of each, highly variable between years (since species extremely sensitive to human disturbance, measured reproductive rates may be artificially low). Most losses of eggs due to infertility or damage during incubation, and of chicks to exposure soon after hatching or later from food shortages; egg and chick predation by large gulls occurs, as does kleptoparasitism throughout chick-rearing period. Adult survival unmeasured, but probably high. Age of first breeding unknown, likely 5-6 years.

Movements. Winters at sea well offshore, often to NC Pacific, normally adjacent to breeding areas except N populations, which move relatively long distances S through Bering Sea into N Pacific. Post-breeding dispersal widespread, occurring mostly solitarily or in pairs, rarely in flocks, at very low densities, some birds moving S to waters off S Japan and S California. Returns to colonies in late Apr and May, with spring migratory movements probably beginning late Feb through Mar, but precise details of pattern and timing unknown. Spring and autumn movements probably complex, requiring further examination.

Status and Conservation. Not globally threatened. Total breeding population estimated at 3,502,000 birds, with c. 764,000 (710,000-810,000) in Asia (c. 22%) and 2,738,000 (2,200,000-3,200,000) in North America (c. 78%); mostly in boreal water zone. Centre of abundance in Aleutians and Alaskan Peninsula region, with 2,340,000 breeding birds (67% of world population), with largest known single colony at Kaligagan I (Unimak) containing c. 375,000 birds. Apart from Sea of Okhotsk (500,000 birds), Kurils (200,000) and SC & SE Alaska (196,000), populations relatively small: Arctic Ocean (4000 birds), Siberian Bering Sea (59,000), Alaskan Bering Sea (99,000), British Columbia (77,000), Washington (23,000), with smallest groups in Oregon (5000 birds), California (under 1000) and Hokkaido (under 1000). Precise data on population levels too few to determine recent trends, but historical record indicates severe declines over last 150 years through most of breeding range, mostly result of introduced predators, i.e. rats (*Rattus*), Arctic fox (*Alopex lagopus*), red fox (*Vulpes vulpes*), mink (*Mustela vison*, *M. lutreola*), feral cats and dogs, and direct human disturbance on breeding islands associated with fur industry and domestic livestock (goats, sheep, rabbits). Best evidence is extirpation of numerous Alaskan colonies by introduced Arctic foxes by late 1930's, and slow, but steady, decreases at colonies in California since 1900. Immediate conservation actions required are: continued eradication and control of alien predators at present and former colonies (particularly in light of recent recolonizations on Alaskan islands following removal of foxes); removal of all domestic livestock from breeding islands, past and present; enhancement of current monitoring system at Alaskan colonies and establishment of similar systems in other regions to enable effective assessment of breeding population size and status; further studies of pelagic ecology of the species to improve understanding of its ecological requirements at sea throughout annual cycle; and protection of colonies during breeding season by minimizing disturbance (e.g. control of tourism, research, fishing activity) through public education and enforcement of existing regulations.
